Asphyxiating Thoracic Dystrophy (Thoracic-Pelvic-Phalangeal Dystrophy)

Pathogenesis.

Also known as *Jeune syndrome,* this condition is an autosomal recessive disorder that results in a constricted and narrow rib cage with generalized chondrodystrophy. Other systems can be involved, including pelvic, phalangeal, and neurologic anomalies along with renal and hepatic disorders.

Clinical Manifestations.

Most patients with this disorder die shortly after birth from respiratory failure, although less aggressive forms have been reported in older children. For those who survive the neonatal period, progressive respiratory failure often ensues owing to impaired lung growth, recurrent pneumonia, and atelectasis originating from the rigid chest wall.

Diagnosis.

Physical examination reveals a narrowed thorax that at birth is much smaller than the head circumference. The ribs are horizontal, and these children have short extremities. Chest radiographs demonstrate a bell-shaped chest cage with short horizontal and flaring ribs and high clavicles.

Treatment.

No specific treatment exists, although thoracoplasty to enlarge the chest wall and long-term mechanical ventilation have been tried with mixed results.

Prognosis.

For some children, improvement in the bony abnormalities occurs with age. However, children younger than 1 yr often succumb to respiratory infection and failure. Progressive renal disease often occurs with older children. Use of vaccines for influenza and other respiratory pathogens is warranted, as is aggressive use of antibiotics for respiratory infections.

Achondroplasia

This condition is inherited as an autosomal dominant disorder that results in disordered growth (see Chapter 684). The pathogenesis is unknown.

Clinical Manifestations.

Recurrent infections, cor pulmonale, and dyspnea are commonly associated with achondroplasia. There is an increased risk of obstructive sleep apnea, although the majority of patients are not affected. Hypoxemia during sleep is a common feature. Onset of restrictive lung disease can begin at a very young age. On examination, the breathing pattern is rapid and shallow with associated abdominal breathing. The anteroposterior diameter of the thorax is reduced. Special growth curves for chest circumference of patients with achondroplasia from birth to 7 yr are available. Three distinct phenotypes exist, with group 1 possessing relative adenotonsillar hypertrophy, group 2 with muscular upper airway obstruction and progressive hydrocephalus, and group 3 with upper airway obstruction without hydrocephalus. Kyphoscoliosis may develop during infancy.

Diagnosis.

Pulmonary function tests reveal a reduced vital capacity that is more pronounced in males. The lungs are small but functionally normal. Chest radiographs demonstrate the decreased anteroposterior diameter along with anterior cupping of the ribs. The degree of foramen magnum involvement correlates with the degree of respiratory dysfunction.

Treatment.

Treatment of sleep apnea, if present, is supportive (see Chapter 369). Physiotherapy and bracing may minimize the complications of kyphosis and of

severe lordosis. Aggressive treatment of respiratory infections and scoliosis is warranted.

Prognosis.

The life span is normal for most children with this condition except for the phenotypic group with hydrocephalus or with severe cervical or lumbar spinal compression.

Kyphoscoliosis: Adolescent Idiopathic Scoliosis and Congenital Scoliosis

Pathogenesis.

Adolescent idiopathic scoliosis (AIS) is characterized by lateral bending of the spine (see Chapter 669). It commonly affects children during their teen years and periods of rapid growth. The cause is unknown. Congenital scoliosis is uncommon, affecting girls more than boys, and is apparent within the first year of life.

Clinical Manifestations.

The pulmonary manifestations of scoliosis may include chest wall restriction leading to a reduction in the total lung capacity. The angle of scoliosis deformity has been correlated with the degree of lung impairment only for those with thoracic curves. Vital capacity, FEV_1 , work capacity, diffusion capacity, chest wall compliance, and Pa_{O_2} decrease as the severity of thoracic curve increases. These findings can be seen in even mild to moderate AIS (Cobb angle < 30 degrees) but do not occur in other nonthoracic curves. Reduction in peripheral muscle function has been associated with AIS through either intrinsic mechanisms or deconditioning. Severe impairment can lead to cor pulmonale or respiratory failure and can occur before age 20 yr.

Children with severe scoliosis, especially boys, may have abnormalities of breathing during sleep, and the resultant periods of hypoxemia may contribute to the eventual development of pulmonary hypertension.

Diagnosis.

Physical examination and an upright posteroanterior radiograph with subsequent measurement of the angle of curvature (Cobb technique) remain the gold standard for assessment. Curves greater than 10 degrees define the presence of scoliosis.

Treatment.

Depending on the extent of the curve and the degree of skeletal maturation, treatment options include reassurance, observation, bracing, and surgery (spinal fusion). Influenza vaccine should be administered given the degree of pulmonary compromise that may co-exist. Because vital capacity is a strong predictor for the development of respiratory failure in untreated AIS, surgical goals are to diminish the scoliotic curve, maintain the correction, and prevent deterioration in pulmonary function. Abnormal vital capacity and total lung capacity, exercise intolerance, and the rate of change of these variables over time should be taken into consideration for the timing of surgical correction. Preoperative assessment of lung function may assist in predicting postsurgical pulmonary difficulties. Many patients undergoing surgical correction may be managed postoperatively without mechanical ventilation. However, even patients with mild scoliosis may have pulmonary compromise immediately after spinal fusion secondary to pain and a body cast that may restrict breathing and interfere with coughing.

Congenital Rib Anomalies

Clinical Manifestations.

Isolated defects of the highest and lowest ribs have minimal clinical pulmonary consequences. Missing midthoracic ribs are associated with the absence of the pectoralis muscle, and lung function can become compromised. Associated kyphoscoliosis and hemivertebrae may accompany this defect. If the rib defect is small, no significant sequelae ensue. When the 2nd to 5th ribs are absent anteriorly,

lung herniation and significant abnormal respiration ensue. The lung is soft and nontender and may be easily reducible on examination. Complicating sequelae include severe lung restriction (secondary to scoliosis), cor pulmonale, and congestive heart failure. Symptoms are often minimal but can cause dyspnea. Respiratory distress is rare in infancy.

Diagnosis.

Chest radiographs demonstrate the deformed and absent ribs with secondary scoliosis. Most rib abnormalities are discovered as incidental findings on a chest film.

Treatment.

If symptoms are severe enough to cause clinical compromise or significant lung herniation, then homologous rib grafting can be performed. Adolescent girls may require cosmetic breast surgery.

Chapter 410 - Neuromuscular Diseases with Pulmonary Consequences

David Gozal

Decreased muscle strength and endurance can affect any skeletal muscle in neuromuscular disorders including those involved in respiratory functions. Of particular concern are those muscles mediating upper airway patency, generation of cough, and lung inflation. Acute respiratory insufficiency is often one of the most prominent clinical presentations of several acute neuromuscular disorders, such as high-level spinal cord injury, poliomyelitis, Guillain-Barré syndrome, and botulism. Although much more insidious in its clinical course, development of respiratory dysfunction constitutes the leading cause of morbidity and mortality in progressive neuromuscular disorders (e.g., Duchenne muscular dystrophy, spinal muscular atrophy, congenital myotonic dystrophy, myasthenia gravis, Charcot-Marie-Tooth disease).

Clinical Manifestations.

Acute respiratory distress with dyspnea, agitation, diaphoresis, and cyanosis should prompt immediate evaluation and therapy. The presence of hypoxemia is easily documented and monitored by pulse oximetry, and the severity of alveolar hypoventilation can be determined by drawing arterial or capillary blood gases. Radiographic assessment may reveal the presence of segmental or lobar atelectasis that may be difficult to differentiate from and will often coincide with a pneumonic infiltrate. In children with progressive neuromuscular disorders, decreases in total lung capacity and vital capacity are usually closely linked to the degree of muscular impairment, and the restrictive lung disease will be further accentuated by the onset and progression of kyphoscoliosis. The increased work of breathing will be further compounded by the decreased chest wall and lung compliance that result from fibrotic changes of the dystrophic chest wall muscles, shortening and stiffening of the unstretched tissues, and widespread microatelectatic changes. Despite the reduction in lung volumes, an increase in

residual volume is frequently observed in patients with neuromuscular disorders and

most likely reflects the disproportionate weakness of expiratory muscles. Such preferential weakness of expiratory muscles precludes, in turn, an effective expiration at lung volumes below functional residual capacity with concomitant reduction of cough and mucociliary clearance efficiency.

Because muscle weakness will reduce maximal expiratory flows, true airflow obstruction may be concealed during standard spirometric maneuvers and requires more sophisticated testing, such as the use of the forced oscillation technique for its detection. Measurement of respiratory muscle strength is an important component of the clinical evaluation of neuromuscular patients, and both maximal inspiratory and expiratory pressures will be reduced, albeit to varying degrees. The major implication of this reduction in respiratory force is the reduced capacity to develop effective clearance of secretions during cough. In the absence of competent mucociliary clearance, plugs of mucus will form and further compromise pulmonary function, especially after the onset of an otherwise benign upper respiratory tract infection. Recurrent or chronic infection and fibrosis will further accelerate the loss of functional lung parenchyma leading to hypoxemia, pulmonary hypertension, and eventually cor pulmonale.

During sleep, and particularly during rapid eye movement sleep, normally occurring decreases in central neural ventilatory output may lead to substantial aggravation of alveolar hypoventilation and hypoxemia. In addition, decreased upper airway motor tone will further promote the occurrence of upper airway obstruction. Thus, patients may complain of daytime sleepiness, fatigue, exertional dyspnea, morning headache and drowsiness, vomiting, difficulty tolerating the supine posture, and frequent need to be repositioned during the night. However, increased clinical awareness of sleep-related disturbances is needed or otherwise many of these symptoms may be misconstrued as related to the neuromuscular disorder.

Treatment.

Interventions are directed at providing supportive therapy rather than curing the underlying abnormalities leading to the particular neuromuscular disease. Close surveillance through periodic history and physical examination are critical and will guide the need for further laboratory testing. Particular attention needs to be paid to the development of personality changes such as irritability, decreased attention span, and fatigue or somnolence, because these may point to the presence of sleep-associated gas exchange abnormalities and sleep fragmentation. Similarly, changes in speech and voice characteristics and the use of alae nasi and other accessory muscles during quiet breathing at rest may provide sensitive indicators of progressive muscle dysfunction and respiratory compromise. Although the frequency of periodic reevaluation needs to

TABLE 410-1 -- Guidelines for Initial Evaluation and Follow-up of Patients with Neuromuscular Disease

Initial Evaluation	Basic Intervention/ Training
History/physical examination/anthropometrics	Nutritional consultation and guidance
Lung function and maximal respiratory pressures (PFT)	Regular chest physiotherapy
Arterial blood gas analysis	Use of percussive devices
Polysomnography	Respiratory muscle training
Exercise testing (in selected cases)	Annual influenza vaccine
If vital capacity > 60% predicted or maximal respiratory pressures > 60?cm H_2 O	Evaluate PFT every 6 mo; chest film and polysomnography yearly
If vital capacity > 60% predicted or maximal respiratory pressures > 60?cm H_2 O	MIP / MEP every 6 mo; polysomnography every 6 mo to yearly

PFT = pulmonary function tests; MIP = maximal inspiratory pressure; MEP = maximal expiratory pressure.

be individually tailored, tentative guidelines are provided in Table 410–1 .

Regular administration of physical therapy, postural drainage, and a variety of manually and mechanically assisted cough maneuvers have demonstrated efficacy in the management of both acute pulmonary exacerbations as well as in long-term maintenance therapy. Parents should become proficient in the administration of such interventions. However, the role of mucolytic agents such as *N*-acetylcysteine or inhaled DNase remains unclear. Respiratory muscle training will improve or at least preserve muscle strength in these children and should be encouraged. Oral or intravenous antibiotic therapy should be administered early in the course of respiratory infections, and inhaled bronchodilators may alleviate any underlying bronchoconstriction. Annual administration of influenza vaccine is generally recommended and pneumococcal vaccine should be strongly considered in younger patients. The roles of theophylline or corticosteroid therapy are not established.

When respiratory insufficiency develops in the setting of neuromuscular disease, as evidenced by abnormal respiratory patterns during sleep or wakefulness, mechanical ventilatory support is needed. Tracheotomy should be avoided for as long as possible. Noninvasive mechanical ventilatory support using either nasal, oral, or face masks is the first line of treatment in both acute and chronic respiratory insufficiency. The beneficial effects of mask ventilation on lung volumes, sleep architecture, mucociliary clearance, and overall quality of life have been clearly demonstrated in patients with neuromuscular disease. Supplemental oxygen may be required to alleviate hypoxemia during either acute or chronic pulmonary insufficiency. Tracheotomy may ultimately become necessary if patients need frequent suctioning of bronchial secretions or when patients require more than 18?hr of ventilatory support a day on a long-term basis. Despite such supportive measures, most chronic neuromuscular disorders will continue to follow their progressive and irreversible course, and social and psychological assistance should be incorporated into the multidisciplinary management of the patients and their families.

Chapter 411 - Extrapulmonary Diseases with Pulmonary Manifestations

Susanna A. McColley

The embryology, anatomy, and physiology of the respiratory system lead to the occurrence of a number of respiratory symptoms that originate from extrapulmonary processes. The respiratory system adapts to metabolic demands and is exquisitely responsive to cortical input; therefore, tachypnea is common in the presence of metabolic stress such as fever, whereas dyspnea may be related to anxiety. Cough most commonly arises from upper or lower respiratory tract disorders, but it can originate from the central nervous system, as with cough tic or psychogenic cough, or it can be a prominent symptom in children with gastroesophageal reflux disease. In contrast, chest pain does not commonly arise from pulmonary processes in otherwise healthy children but more often has a neuromuscular or inflammatory etiology. Cyanosis may be caused by cardiac or hematologic disorders, and dyspnea and exercise intolerance may have a number of extrapulmonary causes. These disorders may be suspected on the basis of the history and physical examination, or they may be considered in children who have atypical findings on diagnostic studies or poor response to usual therapy. Some of the more common causes of such symptoms are listed in Table 411–1 . In evaluating a child or adolescent with respiratory symptoms, it is extremely important to obtain a detailed past medical history, family history, and review of systems to evaluate the possibility of extrapulmonary origin. A comprehensive physical examination is also essential in obtaining clues to extrapulmonary disease.

Disorders of other organ systems, and many systemic diseases, may have significant respiratory system involvement. Although it is most common to encounter these complications in patients with known diagnoses, respiratory system disease is sometimes the sole or most prominent symptom at the time of presentation. For example, acute aspiration during feeding can be the presentation of neuromuscular disease in an infant who initially appears to have normal muscle tone and development. Complications may be life threatening, particularly in patients with immunocompromise. Conversely, the onset of respiratory findings may be insidious; for example, pulmonary vascular involvement in patients with systemic vasculitis may appear as an abnormality in diffusing capacity of the lung for carbon monoxide (DL_{CO})

before the onset of symptoms. Disorders that commonly have respiratory complications are listed in Table 411–2 .

TABLE 411-1 -- **Respiratory Signs and Symptoms Originating from Outside the Respiratory Tract**

Sign Symptom	Nonrespiratory Causes	Pathophysiology	Clues to Diagnosis
Chest pain	Cardiac disease	Inflammation (pericarditis), ischemia (anomalous coronary artery, vascular disease)	Precordial pain, friction rub on examination; exertional pain, radiation to arm or neck
Chest pain	Gastroesophageal reflux disease	Esophageal inflammation and/or spasm	Heartburn, abdominal pain
Cyanosis	Congenital heart disease	Right-to-left shunt	Neonatal onset, lack of response to oxygen
Cyanosis	Methemoglobinemia	Increased levels of metHgb interfere with delivery of oxygen to tissues	Drug or toxin exposure, lack of response to oxygen
Dyspnea	Toxin exposure, drug side effect, or overdose	Variable, but often metabolic acidosis	Drug or toxin exposure confirmed by history or toxicology screen, normal Sp_{O_2}
Dyspnea	Anxiety, panic disorder	Increased respiratory drive and increased perception of respiratory efforts	Occurs during stressful situations, other symptoms of anxiety or depression
Exercise intolerance	Anemia	Inadequate oxygen deliver to tissues	Pallor, tachycardia, history of bleeding, history of inadequate diet
Exercise intolerance	Deconditioning	Self-explanatory	History of inactivity, obesity
Hemoptysis	Nasal bleeding	Posterior flow of bleeding causes appearance of pulmonary origin	History and physical examination suggest nasal source, normal chest examination, and chest radiography
Hemoptysis	Upper gastrointestinal tract bleeding	Hematemesis mimics hemoptysis	History and physical examination suggest gastrointestinal source, normal chest examination and chest radiography
Wheezing, cough, dyspnea	Congenital or acquired cardiac disease	Pulmonary overcirculation (ASD, VSD, PDA), left ventricular dysfunction	Murmur
			Refractory to bronchodilators
			Radiographic changes (prominent pulmonary vasculature, pulmonary edema)
Wheezing, cough	Gastroesophagel reflux disease	Laryngeal and bronchial response to stomach contents	Emesis, pain, heartburn
		?Vagally mediated bronchoconstriction	Refractory to bronchodilators

ASD = atrial septal defect; VSD = ventricular septal defect; PDA = patent ductus arteriosus.

TABLE 411-2 -- **Disorders with Frequent Respiratory Tract Complications**

Underlying Disorder	Respiratory Complications	Diagnostic Tests
Autoimmune disorders	Pulmonary vascular disease, restrictive lung disease, pleural effusion (especially lupus), upper airway disease (Wegener granulomatosis)	Spirometry, lung volume determination, oximetry, DL_{CO}, chest radiography, upper airway endoscopy and/or CT scan
Central nervous system disease (static or progressive)	Aspiration of oral or gastric contents	Chest radiography, videofluoroscopic swallowing study, esophageal pH probe, fiberoptic bronchoscopy
Immunodeficiency	Infection, bronchiectasis	Chest radiography, fiberoptic bronchoscopy, chest CT

Liver disease	Pleural effusion, hepatopulmonary syndrome	Chest radiography, assessment of orthodeoxia
Malignancy and its therapies	Infiltration, metastasis, malignant or infectious effusion, parenchymal infection, graft versus host disease (bone marrow transplant)	Chest radiography, chest CT, fiberoptic bronchoscopy, lung biopsy
Neuromuscular disease (see Part XXVII)	Hypoventilation, atelectasis, pneumonia	Spirometry, lung volume determination, respiratory muscle force measurements
Obesity	Restrictive lung disease, obstructive sleep apnea syndrome	Spirometry, lung volume determination, nocturnal polysomnography

Chapter 412 - Chronic Severe Respiratory Insufficiency

Zehava Noah
Cynthia Budek

Infants, children, and adolescents with disorders of central control of breathing, disease of the airways, residual lung disease after severe respiratory illness, and neuromuscular disorders may develop hypercarbic and/or hypoxemic chronic respiratory failure (Chapter 357.1). In most instances it is possible to identify a primary cause for the respiratory failure; however, many children may have additional factors. Less than 1% of patients admitted to pediatric intensive care units require long-term noninvasive or invasive ventilatory assistance.

ETIOLOGIES

Obstructive Sleep Apnea.

See Chapter 369 .

Central Apnea and Central Hypoventilation Syndromes.

Common conditions include congenital central hypoventilation syndrome (CCHS, Ondine curse); a small percentage of children with myelomeningocele, hydrocephalus, and Arnold-Chiari malformation; and survivors of brainstem tumors. Children with these disorders do not sense hypercapnia, and some of them do not sense hypoxia. Although some children may be severely bradypneic or apneic during some sleep states, the classic finding in CCHS is hypoventilation in the absence of apnea or bradypnea (see Chapter 357.2). Polysomnography confirms the diagnosis by documenting episodes of poor or absent respiratory effort and poor or absent flow during sleep.

Lung Disease.

Common conditions include bronchopulmonary dysplasia (BPD) and children recuperating from adult respiratory distress syndrome (ARDS). Former premature infants recuperating from respiratory distress syndrome may develop BPD (see

Chapter 90.9 and Chapter 408). When extreme, this may progress to respiratory failure.

Severe Tracheo- and/or Bronchomalacia (Airway Malacia).

Conditions associated with airway malacia include tracheoesophageal fistula, innominate artery compression, or pulmonary artery sling after surgical repair (see Chapter 376).

Neuromuscular Weakness.

Disease states resulting in neuromuscular weakness include spinal muscular atrophy (see Chapter 603.2), neurodegenerative diseases, myasthenia gravis, spinal cord injuries, and postinfectious neurologic diseases such as Guillain-Barré syndrome. In addition, children recuperating from severe illness in the intensive care unit often have neuromuscular weakness from suboptimal nutrition coupled with the devastating catabolic effects of severe illness and residual effects of sedatives, analgesics, and muscle relaxants, particularly if steroids were administered. Children with neuromuscular disease have very limited ability to increase ventilation and usually do so by increasing respiratory rate. Because of weakness, retractions may not be observed. In severe illness, some of these children respond to increased respiratory load by becoming apneic. A look of panic, changes in vital signs such as significant tachycardia or bradycardia, and cyanosis may be the only signs of respiratory failure.

EVALUATION

Children with chronic respiratory insufficiency require a thorough evaluation to determine the characteristics and severity of the condition and its effect on physical function (Chapter 357 and Chapter 370). The evaluation should include a complete physical examination, radiologic studies, pulmonary tests, nutritional evaluation, developmental assessment, and analysis of family dynamics. Most children with severe chronic respiratory insufficiency have a combination of factors contributing to their overall clinical status.

LONG-TERM MECHANICAL VENTILATION

Some children with chronic severe respiratory insufficiency will benefit from chronic ventilatory support. The goal of such support is to maintain normal oxygenation and ventilation and minimize work of breathing. Long-term ventilation in the home is a complex, physically demanding, emotionally taxing, and expensive process for the family and for society. It changes the family's way of life, priorities, and relationships. It may adversely affect marital and other relationships.

The prognosis of the disease is a critical factor in deciding to initiate long-term ventilation. The discharge process on ventilatory support should start as soon as the child is medically stable, on equipment that can be maintained in the home. Children with degenerative neuromuscular disease such as type I spinal muscular atrophy (SMA) suffer from respiratory failure very early in life, often triggered by the first respiratory illness. Although some parents decide to provide only palliative end-of-life care for the child with SMA, others choose long-term invasive or noninvasive ventilatory support. Young children

---

with chronic lung disease and airway malacia have the potential to improve their pulmonary function and wean successfully off ventilator support if provided with adequate ventilation, good nutrition, and measures to promote development and prevent further lung injury.

Successful home discharge of a patient receiving mechanical ventilation depends on adequate resources in the community to support the family. Some hospital programs that transition children home on ventilators utilize professional nurses in the home to assist with round-the-clock care. This depends on funding as well as availability of nursing agencies in the community. Housing can be a significant barrier to home discharge because there must be adequate space for the child and caretakers; equipment and supplies; environmental safety including compliance with building and electrical codes; and home modifications for mobility, including ramping and lifts.

Funding for home care is usually a difficult issue for this population of children. If they do have private insurance, coverage for home care benefits is frequently limited. For children eligible for public aid, most states have funds available to meet the special needs of children who are ventilator dependent, although the extent of coverage varies considerably between geographic areas.

RESPIRATORY EQUIPMENT FOR HOME CARE

Modes of mechanical ventilation support are outlined in Chapter 57.4 .

Noninvasive.

A number of machines are available for the delivery of continuous and bilevel positive airway pressure. These machines attach to face masks and are best suited for the treatment of obstructive sleep apnea. Long-term use of these devices in small children may result in midface dysplasia. They occasionally may be used for the delivery of positive pressure through a tracheostomy for infants with tracheobronchomalacia. This type of ventilation has also been used in less severely affected patients with recurrent atelectasis, nighttime hypoventilation, or both.

Rocker Bed.

A rocker bed moves in a longitudinal see-saw motion at a set rate. The child is secured to the bed with a strap. Movement of the bed promotes diaphragm movement. The bed may be an option for children with mild neuromuscular weakness, for instance when recuperating from Guillain-Barré syndrome. This device should not be placed in a home with toddlers or young children because they may get trapped in its mechanism.

Cuirass.

This is a negative pressure device that resembles a turtle shell. It is designed to fit over the anterior chest and provide a tight seal. Cycled negative pressure is applied to the child's chest through a hole in the cuirass. These devices are suitable only for infants and children with mild neuromuscular weakness. A plastic bag–like device that fits snugly around the chest applies the same principle.

Iron Lung.

The iron lung is a cumbersome device that applies negative pressure to the child's body. The child is placed in the iron lung cylinder with the head extending outside the device. A cuff is placed around the neck to minimize air leaks. Negative pressure is cycled within the iron lung, facilitating chest wall movement. Ventilation is disrupted when the device is opened to deliver care. This device is suitable for children with muscular weakness who require ventilation for part of the day. Its main advantage is that it does not require a tracheostomy; however, upper airway obstruction may occur, and this risk requires ongoing evaluation. A lighter version of this device is available for travel.

Diaphragmatic Pacing.

Diaphragmatic pacers may be considered for children with central hypoventilation and those with high spinal cord injury. Surgically, electrodes are placed over the phrenic nerves and a receiver is placed in the subcutaneous tissue. The external pacing device is small and light with antennae secured externally over the receiver. A tracheostomy may be required if there is no coordination between the pacing of the device and the opening of the glottis. Any failure in the electrode pacing wires or the receiver requires surgical intervention.

Positive Pressure Ventilation.

Ideally, a ventilator intended for home use should be lightweight and small, be able to entrain room air, preferably have continuous flow, and have a wide range of settings (pressure, volume, pressure support, and rate) that would allow ventilation from infancy to adulthood. The equipment must also be impervious to electromagnetic interference and be relatively easy to understand and troubleshoot. A variety of ventilators that can be used in the home are available, and familiarity with these devices is necessary to choose the best option for the child.

DISCHARGE PROCESS

The initial discharge process for a child going home on a ventilator is complex. A multidisciplinary, coordinated team approach is needed to develop a comprehensive plan that addresses medical, psychosocial, developmental, educational, and safety issues. The ventilated child must demonstrate medical stability that can be safely managed at home; interventions to maintain stability should be minimal before discharge. The child should be changed to a ventilator suitable for home use that allows portability as well as adequate ventilation. Medical management should also focus on weaning oxygen and ventilator parameters to settings appropriate for home care. Depending on the type of ventilation employed, a tracheostomy may be placed to promote comfort and a stable airway as soon as the decision to chronically ventilate is made.

Nutrition should be optimized to promote growth yet minimize excessive weight gain and carbon dioxide production. The nutritional requirements of a ventilated child are frequently decreased owing to supported work of breathing. The ventilated child often has problems with swallowing from dyscoordination and oral aversion secondary to intubation. Speech therapy should be introduced early to begin oromotor therapy and return of swallow. Many children require gastrostomy tube placement to replace or supplement oral intake. Evaluation and management of reflux and the risk of aspiration should also be considered because these are common problems in ventilated children. Communication devices to augment speech should be part of the planning.

Training of caregivers should be initiated early in the discharge process and be provided by nurses, respiratory care practitioners, and physical, occupational, and speech therapists. Caregivers must be trained in all aspects of care, including tracheostomy care, ventilator management, and cardiopulmonary resuscitation. Their independence in delivery of care at the bedside and while transporting the child should be emphasized. Caregivers must demonstrate their proficiency before the child is discharged.

Community agencies should be identified for provision of home support services. This may include a nursing agency to provide private duty nursing services. It is ideal to train home care nurses about the ventilator and the child's care before home discharge. An equipment vendor should be selected who can provide the ventilator equipment supplies and service. A care conference including the hospital team, funding agency, home nursing agency, equipment vendor, and family caregivers, should take place before discharge. The conference is important for coordination of last minute details and, thus, facilitate a smooth transition to home.

Providing continued support to the child and family after discharge is very important. The pediatrician in the community has

a central role in providing coordination of care, well-child care, and all other medical needs, with the possible exception of ventilatory care. Equally important is the establishment of lines of communication to the medical center and the provision of timely access for advice and troubleshooting during the intervals between multidisciplinary clinic visits.

Part 19 - The Cardiovascular System

Section 1 - *Developmental Biology of the Cardiovascular System*

Daniel Bernstein

Chapter 413 - Cardiac Development

Knowledge of the cellular and molecular mechanisms of cardiac development is necessary to understand congenital heart defects and develop strategies for prevention. Cardiac defects were grouped by common morphologic patterns: abnormalities of the outflow tracts (conotruncal lesions such as the tetralogy of Fallot and truncus arteriosus) and abnormalities of atrioventricular septation (primum atrial septal defect, complete atrioventricular canal defect). These morphologic categories may not, however, provide an understanding of the mechanisms of genetic alterations that lead to congenital heart disease.

413.1 Early Cardiac Morphogenesis

In the early presomite embryo, the first identifiable cardiac precursors are angiogenetic cell clusters arranged on both sides of the embryo's central axis; these clusters form paired cardiac tubes by 18 days of gestation. The paired tubes fuse in the midline on the ventral surface of the embryo to form the primitive heart tube by 22 days. Premyocardial cells, including epicardial cells and cells derived from the neural crest, continue their migration into the region of the heart tube. Regulation of this early phase of cardiac morphogenesis is controlled in part by the interaction of specific signaling molecules or ligands, usually expressed by one cell type, with specific receptors, usually expressed by another cell type. Positional information is conveyed to the developing cardiac mesoderm by retinoids, isoforms of vitamin A, which bind to specific nuclear receptors and regulate gene transcription. Migration of

epithelial cells into the developing heart tube is directed by extracellular matrix proteins, such as fibronectin, interacting with cell surface receptors, such as the integrins. The importance of these ligands is noted clinically by the spectrum of human cardiac teratogenic effects caused by the retinoid-like drug isotretinoin.

As early as 20–22 days, before cardiac looping, the embryonic heart begins to contract and exhibit phases of the cardiac cycle that are surprisingly similar to those in a mature heart. Morphologists have identified segments of the heart tube that were believed to correspond to structures in a mature heart (Fig. 413–1): the sinus venosus and atrium (right and left atria), the primitive ventricle (left ventricle), the bulbus cordis (right ventricle), and the truncus arteriosus (aorta and pulmonary artery). This model is oversimplified, however. Only the trabecular (most heavily muscularized) portions of the left ventricular myocardium are present in the early cardiac tube; the cells that will become the inlet portion of the left ventricle migrate into the cardiac tube at a later stage (after looping is initiated). Even later to appear are the primordial cells that give rise to the great arteries (truncus arteriosus), including cells derived from the neural crest, which are not present until after cardiac looping is complete. Chamber-specific transcription factors participate in the differentiation of the right and left ventricles. The basic helix-loop-helix transcription factor dHAND is expressed in the developing right ventricle; disruption of this gene in mice leads to hypoplasia of the right ventricle. The transcription factor eHAND is expressed in the developing left ventricle and conotruncus.

413.2 Cardiac Looping

At approximately 22–24 days, the heart tube begins to bend ventrally and toward the right (see Fig. 413–1) through unknown biomechanical forces. Looping brings the future left ventricle leftward and in continuity with the sinus venosus (future left and right atria), whereas the future right ventricle is shifted rightward and in continuity with the truncus arteriosus (future aorta and pulmonary artery). This pattern of development explains the relatively common occurrence of the cardiac anomalies double-outlet right ventricle and double-inlet left ventricle and the extreme rarity of double-outlet left ventricle and double-inlet right ventricle (see Chapter 423.5). Cardiac looping, one of the first manifestations of right-left asymmetry in the developing embryo, is critical for the successful completion of cardiac morphogenesis. When cardiac looping is abnormal, the incidence of serious cardiac malformations is high.

Potential mechanisms of cardiac looping include differential growth rates for myocytes on the convex vs the concave surface of the curve, differential rates of programmed cell death (apoptosis), and mechanical forces generated within myocardial cells via their actin cytoskeleton. The signal for this directionality may be contained in a concentration gradient between the right and left sides of the embryo by the expression of critical signaling molecules (members of the tumor growth factor-ß family of peptide growth factors and signaling peptides such as *Sonic hedgehog*). In murine models of abnormal looping, one such defect resides in the dynein gene.

413.3 Cardiac Septation

When looping is complete, the external appearance of the heart is similar to that of a mature heart; internally, the structure resembles a single tube, although it now has several bulges resulting in the appearance of primitive chambers. The common atrium (comprising both the right and left atria) is connected to the primitive ventricle (future left ventricle) via the atrioventricular canal. The primitive ventricle is connected to the bulbus

---

Figure 413.3-1 Timeline of cardiac morphogenesis. (From Larsen WJ: *Essentials of Human Embryology*. New York, Churchill Livingstone, 1998.)

cordis (future right ventricle) via the bulboventricular foramen. The distal portion of the bulbus cordis is connected to the truncus arteriosus via an outlet segment (the conus).

The heart tube now consists of several layers of myocardium and a single layer of endocardium separated by cardiac jelly, an acellular extracellular matrix secreted by the myocardium. Septation of the heart begins at approximately day 26 with the ingrowth of large tissue masses, the endocardial cushions, at both the atrioventricular and conotruncal junctions (see Fig. 413–1). These cushions consist of protrusions of cardiac jelly, which in addition to their role in development, also serve a physiologic function as primitive heart valves. Endocardial cells

---

dedifferentiate and migrate into the cardiac jelly in the region of the endocardial cushions, eventually becoming mesenchymal cells that will form part of the atrioventricular valves.

Complete septation of the atrioventricular canal occurs with fusion of the endocardial cushions. Most of the atrioventricular valve tissue is derived from the ventricular myocardium in a process involving undermining of the ventricular walls. Because this process occurs asymmetrically, the tricuspid valve annulus sits closer to the apex of the heart than the mitral valve annulus does. Physical separation of these two valves produces the atrioventricular septum, the absence of which is the primary common defect in patients with atrioventricular canal defects (see Chapter 419.5). If the process of undermining is incomplete, one of the atrioventricular valves may not separate normally from the ventricular myocardium, a possible cause of Ebstein anomaly (see Chapter 423.7).

Septation of the atria begins at approximately 30 days with growth of the septum primum downward toward the endocardial cushions (see Fig. 413–1). The orifice that remains is the ostium primum. The endocardial cushions then fuse and, together with the completed septum primum, divide the atrioventricular canal into right and left segments. A 2nd opening appears in the posterior portion of the septum primum, the ostium secundum, and it allows a portion of the fetal venous return to the right atrium to pass across to the left atrium. Finally, the septum secundum grows downward, just to the right of the septum primum. Together with a flap of the septum primum,

the ostium secundum forms the foramen ovale, through which fetal blood passes from the inferior vena cava to the left atrium (see Chapter 414).

Septation of the ventricles begins at about day 25 with protrusions of endocardium in both the inlet (primitive ventricle) and outlet (bulbus cordis) segments of the heart. The inlet protrusions fuse into the bulboventricular septum and extend posteriorly toward the inferior endocardial cushion, where they give rise to the inlet and trabecular portions of the interventricular septum. Ventricular septal defects can occur in any portion of the developing interventricular septum (see Chapter 419.6). The outlet or conotruncal septum develops from ridges of cardiac jelly, similar to the atrioventricular cushions. These ridges fuse to form a spiral septum that brings the future pulmonary artery into communication with the anterior and rightward right ventricle and the future aorta into communication with the posterior and leftward left ventricle. Differences in cell growth of the outlet septum lead to lengthening of the segment of smooth muscle beneath the pulmonary valve (conus), a process that separates the tricuspid and pulmonary valves. In contrast, disappearance of the segment beneath the aortic valve leads to fibrous continuity of the mitral and aortic valves. Defects in these processes are responsible for conotruncal and aortic arch defects (truncus arteriosus, tetralogy of Fallot, pulmonary atresia, double-outlet right ventricle, interrupted aortic arch), a group of cardiac anomalies often associated with deletions of the DiGeorge critical region of chromosome 22q11 (see Chapter 423 and Chapter 424).

413.4 Aortic Arch Development

The aortic arch, head and neck vessels, proximal pulmonary arteries, and ductus arteriosus develop from the aortic sac, arterial arches, and dorsal aortae. When the straight heart tube develops, the distal outflow portion bifurcates into the right and left 1st aortic arches, which join the paired dorsal aortae (Fig. 413–2). The dorsal aortae will fuse to form the descending aorta. The proximal aorta from the aortic valve to the left carotid artery arises from the aortic sac. The 1st and 2nd arches largely regress by about 22 days, with the 1st aortic arch giving rise to the maxillary artery and the 2nd to the stapedial and hyoid arteries. The 3rd arches participate in the formation of the innominate artery and the common and internal carotid arteries. The right 4th arch gives rise to the innominate and right subclavian arteries, and the left 4th arch participates in formation of the segment of the aortic arch between the left carotid artery and the ductus arteriosus. The 5th arch does not persist as a major structure in the mature circulation. The 6th arches join the more distal pulmonary arteries, with the right 6th arch giving rise to a portion of the proximal right pulmonary artery and the left 6th arch

Figure 413.4-2 Schematic drawings illustrating the changes that result during transformation of the truncus arteriosus, aortic sac, aortic arches, and dorsal aortae into the adult arterial pattern. The vessels that are not shaded or colored are not derived from these structures. *A*, Aortic arches at 6 wk; by this stage the 1st two pairs of aortic arches have largely disappeared. B, Aortic arches at 7 wk; the parts of the dorsal aortae and aortic arches that normally disappear are indicated by *broken lines*. C, Arterial vessels of a 6-mo-old infant. (From Moore KL, Persaud TVN: *The Developing Human*. Philadelphia, WB Saunders, 1993.)

giving rise to the ductus arteriosus. The aortic arch between the ductus arteriosus and the left subclavian artery is derived from the left-sided dorsal aorta, whereas the aortic arch distal to the left subclavian artery is derived from the fused right and left dorsal aortae. Abnormalities in development of the paired aortic arches are responsible for right aortic arch, double aortic arch, and vascular rings (see Chapter 425.1).

413.5 Cardiac Differentiation

The process by which the totipotential cells of the early embryo become committed to specific cell lineages is called *differentiation*. Precardiac mesodermal cells differentiate into mature cardiac muscle cells with an appropriate complement of cardiac-specific contractile elements, regulatory proteins, receptors, and ion channels. Expression of the contractile protein myosin occurs at an early stage of cardiac development, even before fusion of the bilateral heart primordia. Differentiation in these early mesodermal cells is regulated by signals from the anterior endoderm, a process known as *induction*. Several putative early signaling molecules include fibroblast growth factor, activin, and insulin. Signaling molecules interact with receptors on the cell surface; these receptors activate 2nd messengers, which in turn activate specific *nuclear transcription factors* (GATA-4, MEF2, Nkx, bHLH, and the retinoic acid receptor family) that induce the expression of specific gene products to regulate cardiac differentiation. Some of the primary disorders of cardiac muscle, the cardiomyopathies, may be related to defects in some of these signaling molecules (see Chapter 431).

Developmental processes are chamber specific. Early in development, ventricular myocytes express both ventricular and atrial *isoforms* of several proteins, such as atrial natriuretic peptide (ANP) and myosin light chain (MLC). Mature ventricular myocytes do not express ANP and express only a ventricular-specific MLC 2v isoform, whereas mature atrial myocytes express ANP and an atrial-specific MLC 2a isoform. Heart failure (see Chapter 434 , volume overload (see Chapter 419 and Chapter 421), and pressure overload hypertrophy (see Chapter 420) are associated with a recapitulation of fetal cell phenotypes in which mature myocytes re-express fetal proteins. Because different isoforms have different contractile behavior (fast vs slow activation, high vs low adenosine triphosphatase activity), expression of different isoforms may have important functional consequences.

413.6 Developmental Changes in Cardiac Function

During development, the composition of the myocardium undergoes profound changes that result in an increase in the number and size of myocytes. During prenatal life, this process involves myocyte division *(hyperplasia),* whereas after the 1st few postnatal weeks, subsequent cardiac growth occurs by an increase in myocyte size (*hypertrophy*). The myocytes themselves change shape from round to cylindrical, the proportion of myofibrils (which contain the contractile apparatus) increases, and the myofibrils become more regular in their orientation.

The plasma membrane (known as the *sarcolemma* in myocytes) is the location of the

ion channels and transmembrane receptors that regulate the exchange of chemical information from the cell surface to the cell interior. Ion fluxes through these channels control the processes of depolarization and repolarization. Developmental changes have been described for the sodium-potassium pump, the sodium-hydrogen exchanger, and voltage-dependent calcium channels. As the myocyte matures, extensions of the sarcolemma develop toward the interior of the cell (the t-tubule system), which dramatically increases its surface area and enhances rapid activation of the myocyte. Regulation of the membrane's a- and ß-adrenergic receptors with development enhances the ability of the sympathetic nervous system to control cardiac function as the heart matures.

The *sarcoplasmic reticulum (SR),* a series of tubules surrounding the myofibrils, controls the intracellular calcium concentration. A series of pumps regulate calcium release to the myofibrils for initiation of contraction (ryanodine-sensitive calcium channel) and calcium uptake for initiation of relaxation (adenosine triphosphate–dependent SR calcium pump). In immature hearts, this SR calcium transport system is less well developed, and such hearts consequently have an increased dependence on transport of calcium from outside the cell for contraction. In a mature heart, the majority of calcium to activate contraction comes from the SR. This developmental phenomenon may explain the sensitivity of the infant heart to sarcolemmal calcium channel blockers such as verapamil, which often results in a marked depression in contractility and cardiac arrest (see Chapter 428).

The major contractile proteins (myosin, actin, tropomyosin, and troponin) are organized into the functional unit of cardiac contraction, the sarcomere. Each has several isoforms that are expressed differentially by location (atrium vs ventricle) and by developmental stage (embryo, fetus, newborn, adult).

Changes in myocardial structure and myocyte biochemistry result in easily quantifiable differences in cardiac function with development. In isolated cardiac muscle strips, the force of contraction increases with maturation from fetus to adult. Fetal cardiac function is poorly responsive to changes in both preload (filling volume) and afterload (systemic resistance). The most effective means of increasing ventricular function in a fetus is through increasing the heart rate. After birth and with further maturation, preload and afterload play an increasing role in regulating cardiac function. The rate of cardiac relaxation is also developmentally regulated. The decreased ability of the immature SR calcium pump to remove calcium from the contractile apparatus is manifested as a decreased ability of the fetal heart to enhance relaxation in response to sympathetic stimulation. This inability of the immature myocardium to use preload effectively may partly explain the difficulty that most premature infants have in compensating for the left-to-right shunt through a patent ductus arteriosus (see Chapter 90.3 and Chapter 419.8).

Chapter 414 - The Fetal-to-Neonatal Circulatory Transition

414.1 The Fetal Circulation

The human fetal circulation and its adjustments after birth are for the most part similar to those of other large mammals, although rates of maturation differ. In the fetal circulation, the right and left ventricles exist in a parallel circuit, as opposed to the series circuit of a newborn or adult (Fig. 414–1*A*). In the fetus, the placenta provides for gas and metabolite exchange. The lungs do not provide gas exchange, and vessels in the pulmonary circulation are vasoconstricted. Three cardiovascular structures unique to the fetus are important for maintaining this parallel circulation: the ductus venosus, foramen ovale, and ductus arteriosus.

Oxygenated blood returning from the placenta flows to the fetus through the umbilical vein with a P_{O_2} of about 30–35?mm?Hg. Approximately 50% of the umbilical venous blood enters the hepatic circulation, whereas the rest bypasses the liver and joins the inferior vena cava via the *ductus venosus,* where it partially mixes with poorly oxygenated inferior vena cava blood derived from the lower part of the fetal body. This combined lower body plus umbilical venous blood flow (P_{O_2} of about 26–28?mm?Hg) enters the right atrium and is preferentially directed across the *foramen ovale* to the left atrium (see Fig. 414–1*B*). The blood then flows into the left ventricle and is ejected into the ascending aorta. Fetal superior vena cava blood, which is considerably less oxygenated (P_{O_2} of 12–14?mm?Hg), enters the right atrium and preferentially traverses the tricuspid valve, rather than the foramen ovale, and flows primarily to the right ventricle.

From the right ventricle, the blood is ejected into the pulmonary artery. Because the pulmonary arterial circulation is vasoconstricted, only about 10% of right ventricular outflow enters the lungs. The major portion of this blood (which has a P_{O_2} of about 18–22?mm?Hg) bypasses the lungs and flows through the *ductus arteriosus* into the descending aorta to perfuse the lower part of the fetal body, after which it returns to the placenta via the two umbilical arteries. Thus, the upper part of the fetal body (including the coronary and cerebral arteries and those to the upper extremities) is perfused exclusively from the left ventricle with blood that has a slightly higher P_{O_2} than the blood perfusing the lower part of the fetal body, which is derived mostly from the right ventricle. Only a small volume of blood from the ascending aorta (10% of fetal cardiac output) flows across the aortic isthmus to the descending aorta.

The total fetal cardiac output—the combined ventricular output of both the left and right ventricles—amounts to about 450?mL/kg/min. Approximately 65% of descending aortic blood flow returns to the placenta; the remaining 35% perfuses the fetal organs and tissues. In the sheep fetus, right ventricular output is approximately two times that of the left ventricle. In the human fetus, which has a larger percentage of blood flow going to the brain, right ventricular output is probably closer to 1.3 times left ventricular flow. Thus, during fetal life the right ventricle is not only pumping against systemic blood pressure but is also performing a greater volume of work than the left ventricle is.

414.2 The Transitional Circulation

At birth, mechanical expansion of the lungs and an increase in arterial P_{O_2} result in a rapid decrease in pulmonary vascular resistance. Concomitantly, removal of the low-resistance placental circulation leads to an increase in systemic vascular resistance. The output from the right ventricle now flows entirely into the pulmonary circulation, and because pulmonary vascular resistance becomes lower than systemic vascular resistance, the shunt through the ductus arteriosus reverses and becomes left to right. Over the course of several days, the high arterial P_{O_2} constricts the ductus arteriosus and it closes, eventually becoming the ligamentum arteriosum. The increased volume of pulmonary blood flow returning to the left atrium increases left atrial volume and pressure sufficiently to close the foramen ovale functionally, although the foramen may remain probe patent.

Removal of the placenta from the circulation also results in closure of the ductus venosus. The left ventricle is now coupled to the high-resistance systemic circulation, and its wall thickness and mass begin to increase. In contrast, the right ventricle is now coupled to the low-resistance pulmonary circulation, and its wall thickness and mass decrease slightly. The left ventricle, which in the fetus pumped blood only to the upper part of the body and brain, must now deliver the entire systemic cardiac output (approximately 350?mL/kg/min), an almost 200% increase in output. This marked increase in left ventricular performance is achieved through a combination of hormonal and metabolic signals, including an increase in the level of circulating catecholamines and the myocardial receptors (ß-adrenergic) through which catecholamines have their effect.

When congenital structural cardiac defects are superimposed on these dramatic physiologic changes, they often impede this smooth transition and markedly increase the burden on the newborn myocardium. In addition, because the ductus arteriosus and foramen ovale do not close completely at birth, they may remain patent in certain congenital cardiac lesions. Patency of these fetal pathways may either provide a lifesaving pathway for blood to bypass a congenital defect (e.g., a patent ductus in pulmonary atresia or coarctation of the aorta or a foramen ovale in transposition of the great vessels) or present an additional stress to the circulation (patent ductus arteriosus in a premature infant, pathway for right-to-left shunting in infants with pulmonary hypertension). Therapeutic agents may either maintain these fetal pathways (e.g., prostaglandin E_1) or hasten their closure (indomethacin).

414.3 The Neonatal Circulation

At birth, the fetal circulation must immediately adapt to extrauterine life as gas exchange is transferred from the placenta to the lung (see Chapter 90.1). Some of these changes are virtually instantaneous with the 1st breath, whereas others develop over a period of hours or days. After an initial slight fall in systemic blood pressure, a progressive rise occurs with increasing age. The heart rate slows as a result of a baroreceptor response to an increase in systemic vascular resistance when the placental circulation is eliminated. The average central aortic pressure in a term neonate is 75/50?mm?Hg.

With the onset of ventilation, pulmonary vascular resistance is markedly decreased as a consequence of both active (P_{O_2} related) and passive (mechanical related) vasodilation. In a normal neonate, closure of the ductus arteriosus and the fall in pulmonary vascular resistance result in a decrease in pulmonary arterial and right ventricular pressure. The major decline in pulmonary resistance from the high fetal levels to the low “adult” levels in the human infant at sea level usually occurs within the 1st 2–3 days but may be prolonged for 7 days or more. Over the 1st several weeks of life, pulmonary vascular resistance decreases even further secondary to remodeling of the pulmonary vasculature, including thinning of the vascular smooth

Figure 414.3-1 *A*, The human circulation before birth (partly after Dawes). *Black shading* indicates more oxygenated blood, and *arrows* indicate the direction of flow. *B*, Percentages of combined ventricular output that return to the fetal heart, that are ejected by each ventricle, and that flow through the main vascular channels. Figures are those obtained from study of late-gestation lambs. (From Rudolph AM: *Congenital Diseases of the Heart*. Chicago, Year Book, 1974.)

muscle and recruitment of new vessels. This decrease in pulmonary vascular resistance significantly influences the timing of the clinical appearance of many congenital heart lesions that are dependent on the relative systemic and pulmonary vascular resistance. For example, the left-to-right shunt through a ventricular septal defect may be minimal during the 1st wk after birth when pulmonary vascular resistance is still somewhat high. As pulmonary resistance decreases over the next week or two, the volume of the left-to-right shunt through the ventricular septal defect increases and eventually leads to symptoms of congestive heart failure.

Significant differences between the neonatal circulation and that of older infants may be summarized as follows: (1) right-to-left or left-to-right shunting may persist across the patent foramen ovale; (2) in the presence of cardiopulmonary disease, continued patency of the ductus arteriosus may allow left-to-right, right-to-left, or bidirectional shunting; (3) the neonatal pulmonary vasculature constricts more vigorously in response to hypoxemia, hypercapnia, and acidosis; (4) the wall thickness and muscle mass of the neonatal left and right ventricles are almost equal; and (5) newborn infants at rest have relatively high oxygen consumption, which is associated with relatively high cardiac output. The newborn cardiac output (about 350?mL/kg/min) falls over the 1st 2 mo of life to about 150?mL/kg/min and then more gradually to the normal adult cardiac output of about 75?mL/kg/min. The high percentage of fetal hemoglobin present in the newborn may actually interfere with delivery of oxygen to tissues in the neonate, so increased cardiac output is needed for adequate delivery of oxygen (see Chapter 90.1).

The foramen ovale is functionally closed by the 3rd mo of life, although it is possible to pass a probe through the overlapping flaps in a large percentage of children and in 15–25% of adults. Functional closure of the ductus arteriosus is usually complete by 10–15?hr in a normal neonate, although the ductus may remain patent much longer in the presence of congenital heart disease, especially when associated with cyanosis. In premature newborn infants, an evanescent systolic murmur with late accentuation or a continuous murmur may be audible, and in the context of respiratory distress syndrome, the presence of a patent ductus arteriosus should be suspected (see Chapter 90.3).

The normal ductus arteriosus differs morphologically from the adjoining aorta and pulmonary artery in that the ductus has a significant amount of circularly arranged smooth muscle in its medial layer. During fetal life, patency of the ductus arteriosus appears to be maintained by the combined relaxant effects of low oxygen tension and endogenously produced prostaglandins, specifically prostaglandin E_2 . In a full-term neonate, oxygen is the most important factor controlling ductal closure. When the P_{O_2} of the blood passing through the ductus reaches about 50?mm?Hg, the ductal wall constricts. The effects of oxygen on ductal smooth muscle may be direct or mediated by its effects on prostaglandin synthesis. Gestational age also appears to play an important role; the ductus of a premature infant is less responsive to oxygen, even though its musculature is developed.

414.4 Persistent Pulmonary Hypertension of the Neonate (Persistence of Fetal Circulatory Pathways)

Section 2 - *Evaluation of the Cardiovascular System*

Daniel Bernstein

Chapter 415 - History and Physical Examination

The importance of the history and physical examination cannot be overemphasized in the evaluation of infants and children with suspected cardiovascular disorders. Patients may require further laboratory evaluation and eventual treatment, or the family may be reassured that no significant problem exists. Although the ready availability of echocardiography may entice the clinician to skip these preliminary steps, an initial evaluation by a skilled cardiologist is preferred for several reasons: (1) a cardiac examination allows the cardiologist to guide the echocardiographic evaluation toward confirming or eliminating specific diagnoses, thereby increasing its accuracy; (2) because most childhood murmurs are innocent, evaluation by a pediatric cardiologist can eliminate unnecessary and expensive laboratory tests; and (3) the cardiologist's knowledge and experience are important in reassuring the patient's family and preventing unnecessary restrictions on healthy physical activity.

History.

A comprehensive cardiac history starts with details of the perinatal period, including the presence of cyanosis, respiratory distress, or prematurity. Maternal complications such as gestational diabetes, medications, systemic lupus erythematosus, or substance abuse can be associated with cardiac problems. If cardiac symptoms began during infancy, the timing of the initial symptoms should be noted to provide important clues about the specific cardiac condition.

Many of the symptoms of congestive heart failure in infants and children are age specific. In infants, *feeding difficulties* are common. Inquiry should be made about the frequency of feeding and either the volume of each feeding or the time spent on each breast. An infant with heart failure often takes less volume per feeding and become dyspneic or diaphoretic while sucking. After falling asleep exhausted, the baby, inadequately fed, will awaken for the next feeding after a brief time. This cycle continues around the clock and must be carefully differentiated from colic or other feeding disorders. Additional symptoms and signs include those of *respiratory distress:* rapid breathing, nasal flaring, cyanosis, and chest retractions. In older children, heart failure may be manifested as *exercise intolerance,* difficulty keeping

up with peers during sports or need for a nap after coming home from school, and poor growth. Eliciting a history of fatigue in an older child requires questions about age-specific activities, including stair climbing, walking, bicycle riding, physical education class, and competitive sports; information should be obtained regarding more severe manifestations such as orthopnea and nocturnal dyspnea.

Cyanosis at rest is often overlooked by parents; it may be mistaken for a normal individual variation in coloration. Cyanosis during crying or exercise, however, is more often noted as abnormal by observant parents. Many infants and toddlers turn “blue around the lips” when crying vigorously or during breath-holding spells; this condition must be carefully differentiated from cyanotic heart disease by inquiring about inciting factors, the length of episodes, and whether the tongue and mucous membranes also appear cyanotic. Newborns have cyanotic extremities **(acrocyanosis)** when undressed and cold, and this response to cold must be carefully differentiated from true cyanosis.

Chest pain is an unusual manifestation of cardiac disease in pediatric patients, although it is a frequent cause for referral to a pediatric cardiologist, especially in adolescents. Nonetheless, a careful history, physical examination, and if indicated, laboratory or imaging tests will assist in identifying the cause of chest pain (Box 415–1).

Cardiac disease may be a manifestation of a known congenital malformation syndrome with typical physical findings (Table 415–1) or a manifestation of a generalized disorder affecting the heart and other organ systems (Table 415–2). *Extracardiac malformations* may be noted in 20–45% of infants with congenital heart disease. Between 5 and 10% of patients have a known chromosomal abnormality; this percentage will increase as our knowledge of specific gene defects linked to congenital heart disease increases. A careful family history may also reveal early coronary artery disease or stroke (familial hypercholesterolemia or thrombophilia), generalized muscle disease (muscular dystrophy, dermatomyositis, familial or metabolic cardiomyopathy), or relatives with congenital heart disease.

General Physical Examination.

After general assessment of the patient, specific attention is directed toward the presence of cyanosis, abnormalities in growth, and any evidence of respiratory distress. Evaluation of a murmur must always be performed in the context of other physical findings. Frequently, associated findings, such as the quality of the pulses or the presence of a

Box 415-1. Differential Diagnosis of Chest Pain in Pediatric Patients

MUSCULOSKELETAL (COMMON)

- Trauma (accidental, abuse)
- Exercise, overuse injury (strain, bursitis)
- Costochondritis (Tietze syndrome)
- Herpes zoster (cutaneous)
- Pleurodynia
- Fibrositis
- Slipping rib
- Sickle cell anemia vaso-occlusive crisis
- Osteomyelitis (rare)
- Primary or metastatic tumor (rare)

PULMONARY (COMMON)

- Pneumonia
- Pleurisy
- Asthma
- Chronic cough
- Pneumothorax
- Infarction (sickle cell anemia)
- Foreign body
- Embolism (rare)
- Pulmonary hypertension (rare)
- Tumor (rare)

Embolism (rare)

Pulmonary hypertension (rare)

Tumor (rare)

Bronchiectasis

GASTROINTESTINAL (LESS COMMON)

Esophagitis (gastroesophageal reflux, infectious, pill)

Esophageal foreign body

Esophageal spasm

Cholecystitis

Subdiaphragmatic abscess

Perihepatitis (Fitz-Hugh-Curtis syndrome)

Peptic ulcer disease

CARDIAC (LESS COMMON)

Pericarditis

Postpericardiotomy syndrome

Endocarditis

Cardiomyopathy

Mitral valve prolapse

Aortic or subaortic stenosis

Arrhythmias

Marfan syndrome (dissecting aortic aneurysm)

Kawasaki disease

Cocaine, sympathomimetic ingestion

Angina (familial hypercholesterolemia, anomalous coronary artery)

Angina (familial hypercholesterolemia, anomalous coronary artery)

IDIOPATHIC (COMMON)

Anxiety, hyperventilation

Panic disorder

OTHER (LESS COMMON)

Spinal cord or nerve root compression

Breast-related pathologic condition

Castleman disease (lymph node neoplasm)

ventricular heave, provide important clues to a specific cardiac diagnosis.

Accurate measurement of *height* and *weight* and plotting on a standard growth chart are important because both cardiac failure and chronic cyanosis result in failure to thrive. Growth failure is usually manifested predominantly by poor weight gain; if length or head circumference is also affected, additional congenital malformations or metabolic disorders may be present.

Mild *cyanosis* may be too subtle for early detection, and clubbing of the fingers and toes is not usually manifested until late in the 1st yr of life, even in the presence of severe arterial oxygen desaturation. Cyanosis is best observed over the nail beds, lips, tongue, and mucous membranes. **Differential cyanosis,** manifested as blue lower extremities and pink upper extremities (usually the right arm), is seen with right-to-left shunting across a ductus arteriosus in the presence of coarctation or an interrupted aortic arch. Circumoral cyanosis or blueness around the forehead may be the result of prominent venous plexuses in these areas rather than decreased arterial oxygen saturation. The extremities of infants often turn blue when the infant is unwrapped and cold (**acrocyanosis**), and this condition can be distinguished from central cyanosis by examination of the tongue and mucous membranes.

Heart failure in infants and children results in some degree of hepatomegaly and occasionally splenomegaly. The sites of peripheral edema are age dependent. In infants, edema is usually seen around the eyes and over the flanks, especially after first waking in the morning. Older children and teenagers manifest both periorbital edema and pedal edema. A frequent initial complaint in these older patients is that their clothes no longer fit.

The *heart rate* of newborn infants is rapid and subject to wide fluctuations (Table 415–3). The average rate ranges from 120 to 140 beats/min and may increase to

170+ beats/min during crying and activity or drop to 70–90 beats/min during sleep. As the child grows older, the average pulse rate decreases and may be as low as 40 beats/min in athletic adolescents. Persistent tachycardia (>200 beats/min in neonates, 150 beats/min in infants, or 120 beats/min in older children), bradycardia, or an irregular heartbeat other than sinus arrhythmia requires investigation to exclude pathologic arrhythmias (see Chapter 428).

Careful evaluation of the character of the pulses is an important early step in the physical diagnosis of congenital heart disease. A wide pulse pressure with bounding pulses may suggest an aortic runoff lesion such as patent ductus arteriosus, aortic insufficiency, an arterial-venous communication, or increased cardiac output secondary to anemia, anxiety, or conditions associated with increased catecholamine or thyroid hormone secretion. The presence of diminished pulses in all extremities is associated with pericardial tamponade, left ventricular outflow obstruction, or cardiomyopathy. The radial and femoral pulses should always be palpated simultaneously. Normally, the femoral pulse should be appreciated immediately before the radial pulse. In older children with coarctation of the aorta, blood flow to the descending aorta may channel through collateral vessels and result in the femoral pulse being delayed until after the radial pulse (radial-femoral delay).

Blood pressure should be measured in the arms as well as in the legs, the latter on at least one occasion to be certain that coarctation of the aorta is not overlooked. Palpation of the femoral or dorsalis pedis pulse, or both, is not reliable alone to exclude coarctation. In older children, a mercury sphygmomanometer with a cuff that covers approximately two thirds of the upper part of the arm or leg may be used for blood pressure measurement. A cuff that is too small results in falsely high readings, whereas a cuff that is too large records slightly decreased pressure. Pediatric clinical facilities should be equipped with 3, 5, 7, 12, and 18?cm cuffs to accommodate the large spectrum of pediatric patient sizes. The 1st Korotkoff sounds indicate systolic pressure. As cuff pressure is slowly decreased, the sounds usually become muffled before they disappear. Diastolic pressure may be recorded when the sounds become muffled (preferred) or when they disappear altogether; the former is usually slightly higher and the latter slightly lower than true diastolic pressure. For lower extremity blood pressure determination, the stethoscope is placed over the popliteal artery. Ordinarily, the pressure recorded in the legs with the cuff technique is about 10?mm?Hg higher than that in the arms.

In infants, blood pressure can be determined by auscultation, palpation, or an oscillometric (Dinamap) device, which if used properly, provides accurate measurements in infants as well as older children.

Blood pressure varies with the age of the child and is closely related to height and weight. Significant increases occur during adolescence, and many temporary variations take place before the more stable levels of adult life are attained. Exercise, excitement, coughing, crying, and struggling may raise the systolic

TABLE 415-1 -- Congenital Malformation Syndromes Associated with Congenital Heart Disease

Syndrome	Features
Chromosomal Disorders	
Trisomy 21 (Down syndrome)	Endocardial cushion defect, VSD, ASD
Trisomy 21p (cat eye syndrome)	Miscellaneous, total anomalous pulmonary venous return
Trisomy 18	VSD, ASD, PDA, coarctation of aorta, bicuspid aortic or pulmonary valve
Trisomy 13	VSD, ASD, PDA, coarctation of aorta, bicuspid aortic or pulmonary valve
Trisomy 9	Miscellaneous
XXXXY	PDA, ASD
Penta X	PDA, VSD
Triploidy	VSD, ASD, PDA
XO (Turner syndrome)	Bicuspid aortic valve, coarctation of aorta
Fragile X	Mitral valve prolapse, aortic root dilatation
Duplication 3q2	Miscellaneous
Deletion 4p	VSD, PDA, aortic stenosis
Deletion 9p	Miscellaneous
Deletion 5p (cri du chat syndrome)	VSD, PDA, ASD
Deletion 10q	VSD, TOF, conotruncal lesions[*]
Deletion 13q	VSD
Deletion 18q	VSD
Syndrome Complexes	
CHARGE association (coloboma, *h*eart, *a*tresia choanae, *r*etardation, *g*enital and *e*ar anomalies)	VSD, ASD, PDA, TOF, endocardial cushion defect
DiGeorge sequence, CATCH 22 (cardiac defects, *a*bnormal facies, *t*hymic aplasia, *c*left palate, and *h*ypocalcemia)	Aortic arch anomalies, conotruncal anomalies
Alagille syndrome (arteriohepatic dysplasia)	Peripheral pulmonic stenosis
VATER association (vertebral, *a*nal, *t*racheo*e*sophageal, *r*adial, and *r*enal anomalies)	VSD, TOF, ASD, PDA
FAVS (*f*acio-*a*uriculo-*v*ertebral *s*pectrum)	TOF, VSD

CHILD (congenital *h*emidysplasia with *i*chthyosiform *e*rythroderma, *l*imb *d*efects)	Miscellaneous
Mulibrey nanism (*m*uscle, *l*iver, *b*rain, *e*ye)	Pericardial thickening, constrictive pericarditis
Asplenia syndrome	Complex cyanotic heart lesions with decreased pulmonary blood flow, transposition of great arteries, anomalous pulmonary venous return, dextrocardia, single ventricle, single atrioventricular valve
Polysplenia syndrome	Acyanotic lesions with increased pulmonary blood flow, azygos continuation of inferior vena cava, partial anomalous pulmonary venous return, dextrocardia, single ventricle, common atrioventricular valve
PHACE syndrome (*p*osterior brain fossa anomalies, facial *h*emangiomas, *a*rterial anomalies, *c*ardiac anomalies and aortic *c*oarctation, *e*ye anomalies)	VSD, PDA, coarctation of aorta, arterial aneurysms
Teratogenic Agents	
Congenital rubella	PDA, peripheral pulmonic stenosis
Fetal hydantoin syndrome	VSD, ASD, coarctation of aorta, PDA
Fetal alcohol syndrome	ASD, VSD
Fetal valproate effects	Coarctation of aorta, hypoplastic left side of heart, aortic stenosis, pulmonary atresia, VSD
Maternal phenylketonuria	VSD, ASD, PDA, coarctation of aorta
Retinoic acid embryopathy	Conotruncal anomalies
Others	
Apert syndrome	VSD
Autosomal dominant polycystic kidney disease	Mitral valve prolapse
Carpenter syndrome	PDA
Conradi syndrome	VSD, PDA
Crouzon disease	PDA, coarctation of aorta
Cutis laxa	Pulmonary hypertension, pulmonic stenosis
de Lange syndrome	VSD
Ellis-van Creveld syndrome	Single atrium, VSD
Holt-Oram syndrome	ASD, VSD, 1st-degree heart block
Infant of diabetic mother	Hypertrophic cardiomyopathy, VSD, conotruncal anomalies
Kartagener syndrome	Dextrocardia
Meckel-Gruber syndrome	ASD, VSD
Noonan syndrome	Pulmonic stenosis, ASD, cardiomyopathy
Pallister-Hall syndrome	Endocardial cushion defect
Rubinstein-Taybi syndrome	VSD
Scimitar syndrome	Hypoplasia of right lung, anomalous pulmonary venous return to inferior vena cava
Smith-Lemli-Opitz syndrome	VSD, PDA
TAR syndrome (*t*hrombocytopenia and *a*bsent *r*adius)	ASD, TOF
Treacher Collins syndrome	VSD, ASD, PDA
Williams syndrome	Supravalvular aortic stenosis, peripheral pulmonic stenosis

VSD = ventricular septal defect; ASD = atrial septal defect; PDA = patent ductus arteriosus;TOF = tetralogy of Fallot.

**Conotruncal =TOF, pulmonary atresia, truncus arteriosus, transposition of great arteries.*

pressure of infants and children as much as 40–50?mm?Hg greater than their usual levels. Variability in blood pressure in children of approximately the same age and body build should be expected, and serial measurements should always be obtained when evaluating a patient with hypertension (Figs. 415–1 and 415–2).

Though of little use in infants, in cooperative older children, inspection of the *jugular venous pulse* wave provides information about *central venous* and right atrial pressure. The neck veins should be inspected with the patient sitting at a 90-degree angle. The external jugular vein should not be visible above the clavicles unless central venous pressure is elevated. Increased

TABLE 415-2 -- **Cardiac Manifestations of Systemic Diseases**

Systemic Disease	Cardiac Complications
Inflammatory Disorders	
Sepsis	Hypotension, myocardial dysfunction, pericardial effusion, pulmonary hypertension

Juvenile rheumatoid arthritis	Pericarditis, rarely myocarditis
Systemic lupus erythematosus	Pericarditis, Libman-Sacks endocarditis, coronary arteritis, coronary atherosclerosis (with steroids), congenital heart block
Scleroderma	Pulmonary hypertension, myocardial fibrosis, cardiomyopathy
Dermatomyositis	Cardiomyopathy, arrhythmias, heart block
Kawasaki disease	Coronary artery aneurysm and thrombosis, myocardial infarction, myocarditis, valvular insufficiency
Sarcoidosis	Granuloma, fibrosis, amyloidosis, biventricular hypertrophy, arrhythmias
Lyme disease	Arrhythmias, myocarditis
Löffler hypereosinophilic syndrome	Endomyocardial disease
Inborn Errors of Metabolism	
Refsum disease	Arrhythmia, sudden death
Hunter-Hurler syndrome	Valvular insufficiency, heart failure, hypertension
Fabry disease	Mitral insufficiency, coronary artery disease with myocardial infarction
Glycogen storage disease IIa (Pompe disease)	Short PR interval, cardiomegaly, heart failure, arrhythmias
Carnitine deficiency	Heart failure, cardiomyopathy
Gaucher disease	Pericarditis
Homocystinuria	Coronary thrombosis
Alkaptonuria	Atherosclerosis, valvular disease
Morquio-Ullrich syndrome	Aortic incompetence
Scheie syndrome	Aortic incompetence
Connective Tissue Disorders	
Arterial calcification of infancy	Calcinosis of coronary arteries, aorta
Marfan syndrome	Aortic and mitral insufficiency, dissecting aortic aneurysm, mitral valve prolapse
Congenital contractural arachnodactyly	Mitral insufficiency or prolapse
Ehlers-Danlos syndrome	Mitral valve prolapse, dilatated aortic root
Osteogenesis imperfecta	Aortic incompetence
Pseudoxanthoma elasticum	Peripheral arterial disease
Neuromuscular Disorders	
Friedreich ataxia	Cardiomyopathy
Duchenne dystrophy	Cardiomyopathy, heart failure
Tuberous sclerosis	Cardiac rhabdomyoma
Familial deafness	Occasionally arrhythmia, sudden death
Neurofibromatosis	Pulmonic stenosis, pheochromocytoma, coarctation of aorta
Riley-Day syndrome	Episodic hypertension, postural hypotension
Von Hippel-Lindau disease	Hemangiomas, pheochromocytomas
Endocrine-Metabolic Disorders	
Graves disease	Tachycardia, arrhythmias, heart failure
Hypothyroidism	Bradycardia, pericardial effusion, cardiomyopathy, low-voltage electrocardiogram
Pheochromocytoma	Hypertension, myocardial ischemia, myocardial fibrosis, cardiomyopathy
Carcinoid	Right-sided endocardial fibrosis
Hematologic Disorders	
Sickle cell anemia	High-output heart failure, cardiomyopathy, cor pulmonale
Thalassemia major	High-output heart failure, hemochromatosis
Hemochromatosis (1st or 2nd degree)	Cardiomyopathy
Others	
Appetite suppressants (fenfluramine and dexfenfluramine)	Cardiac valvulopathy, pulmonary hypertension
Cockayne syndrome	Atherosclerosis
Familial dwarfism and nevi	Cardiomyopathy
Jervell and Lange-Nielsen syndrome	Prolonged QT interval, sudden death
Kearns-Sayre syndrome	Heart block
LEOPARD syndrome (lentiginosis)	Pulmonic stenosis, prolonged QT interval
Progeria	Accelerated atherosclerosis
Rendu-Osler-Weber syndrome	Arteriovenous fistula (lung, liver, mucous membrane)
Romano-Ward syndrome	Prolonged QT interval, sudden death
Weill-Marchesani syndrome	Patent ductus arteriosus
Werner syndrome	Vascular sclerosis, cardiomyopathy

LEOPARD = multiple *l* entigines, *e*lectrocardiographic conduction abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitals, *r*etardation of growth, sensorineural *d*eafness.

venous pressure transmitted to the internal jugular vein may appear as venous pulsations without visible distention; such pulsation is not seen in normal children reclining at an angle of 45 degrees. Because the great veins are in direct communication with the right atrium, changes in pressure and the volume of this chamber are also transmitted to the veins. The one exception occurs in superior vena cava obstruction, in which venous pulsatility is lost.

Cardiac Examination.

The heart should be examined in a systematic manner starting with *inspection* and *palpation.* A **precordial bulge** to the left of the sternum with increased precordial activity suggests cardiac enlargement; such bulges can often best be appreciated by having the child lay supine with the examiner looking up from the child's feet. A **substernal thrust** indicates the presence of right ventricular enlargement, whereas an **apical heave** is noted with left ventricular hypertrophy. A **hyperdynamic precordium**

TABLE 415-3 -- **Pulse Rates at Rest**

Age	Lower Limits of Normal		Average		Upper Limits of Normal	
Newborn	70/min		125/min		190/min	
1–11 mo	80		120		160	
2yr	80		110		130	
4yr	80		100		120	
6yr	75		100		115	
8yr	70		90		110	
10yr	70		90		110	
	Girls	***Boys***	***Girls***	***Boys***	***Girls***	***Boys***
12yr	70	65	90	85	110	105
14yr	65	60	85	80	105	100
16yr	60	55	80	75	100	95
18yr	55	50	75	70	95	90

suggests a volume load such as that found with a large left-to-right shunt, although it may be normal in a thin patient. A **silent precordium** with a barely detectable apical impulse suggests pericardial effusion or severe cardiomyopathy; it may be normal in an obese patient.

The relationship of the apical impulse to the midclavicular line is also helpful in the estimation of cardiac size: the apical impulse moves laterally and inferiorly with enlargement of the left ventricle. Right-sided apical impulses signify dextrocardia, tension pneumothorax, or left-sided thoracic space-occupying lesions (e.g., diaphragmatic hernia).

Thrills are the palpable equivalent of murmurs and correlate with the area of maximal auscultatory intensity of the murmur. It is important to palpate the suprasternal notch and neck for **aortic bruits,** which may indicate the presence of aortic stenosis or, when faint, pulmonary stenosis. Right lower sternal border and apical systolic thrills are characteristic of ventricular septal defect and mitral insufficiency, respectively. Diastolic thrills are occasionally palpable in the presence of atrioventricular valve stenosis. The timing and localization of thrills should be carefully noted.

Auscultation is an art that improves with practice. The diaphragm of the stethoscope is placed firmly on the chest for high-pitched sounds; a lightly placed bell is optimal for low-pitched sounds. The physician should initially concentrate on the characteristics of the individual heart sounds and their variation with respirations and later concentrate on murmurs. The patient should be supine, lying quietly, and breathing normally. The 1st heart sound is best heard at the apex, whereas the 2nd heart sound should be evaluated at the upper left and right sternal borders. The 1st heart sound is caused by closure of the atrioventricular valves (mitral and tricuspid); the 2nd sound is caused by closure of the semilunar valves (aortic and pulmonary; Fig. 415–3). During inspiration, the decrease in intrathoracic pressure results in increased filling of the right side of the heart, which leads to an increased right ventricular ejection time and thus delayed closure of the pulmonary valve; consequently, splitting of the 2nd heart sound increases during inspiration and decreases during expiration.

Often, the 2nd heart sound appears to be single during expiration. The presence of a normally split 2nd sound is strong evidence against the diagnosis of atrial septal defect, defects associated with pulmonary arterial hypertension, severe pulmonary valve stenosis, aortic and pulmonary atresia, and truncus arteriosus. Wide splitting is noted in atrial septal defect, pulmonary stenosis, Ebstein anomaly, total anomalous pulmonary venous return, and right bundle branch block. An accentuated pulmonic component of the 2nd sound with narrow splitting is a sign of pulmonary hypertension. A single 2nd sound occurs in pulmonary or aortic atresia or severe stenosis, truncus arteriosus, and often in transposition of the great arteries.

A 3rd heart sound is best heard with the bell at the apex in mid-diastole. A 4th sound occurring in conjunction with atrial contraction may be heard just before the 1st heart sound in late diastole. The 3rd sound may be normal in an adolescent with a relatively slow heart rate, but in a patient with the clinical signs of heart failure and tachycardia, it may be heard as a gallop rhythm and may merge with a 4th heart sound, a finding known as a *summation gallop.* A **gallop** rhythm is attributed to poor compliance of the ventricle, and exaggeration of the normal 3rd sound is associated

with ventricular filling.

Ejection clicks, which are heard in early systole, may be related to dilatation of the aorta or pulmonary artery or to a mildly to moderately stenotic semilunar valve. They are heard so close to the 1st heart sound that they may be mistaken for a split 1st sound. Aortic ejection clicks are best heard at the left middle to right upper sternal border and are constant in intensity. They occur in conditions in which the aortic valve is stenotic or the aorta is dilated (tetralogy of Fallot, truncus arteriosus). Pulmonary ejection clicks, which are associated with mild to moderate pulmonary stenosis, are best heard at the left middle to upper sternal border and vary with respirations, often disappearing with inspiration. Split 1st heart sounds are usually heard best at the lower left sternal border. A midsystolic click heard at the apex, often preceding a late systolic murmur, suggests mitral valve prolapse.

Murmurs should be described according to their intensity, pitch, timing (systolic or diastolic), variation in intensity, time to peak intensity, area of maximal intensity, and radiation to other areas. Auscultation for murmurs should be carried out across the upper precordium, down the left or right sternal border, and out to the apex and left axilla. Auscultation should also always be performed in the right axilla and over the back. **Systolic murmurs** are classified as ejection, pansystolic, or late systolic according to the timing of the murmur in relation to the 1st and 2nd heart sounds. The intensity of systolic murmurs is graded from I to VI: I, barely audible; II, medium intensity; III, loud but no thrill; IV, loud with a thrill; V, very loud but still requiring positioning of the stethoscope at least partly on the chest; and VI, so loud that the murmur can be heard with the stethoscope off the chest.

Systolic ejection murmurs start a short time after a well-heard 1st heart sound, increase in intensity, peak, and then decrease in intensity; they usually end before the 2nd sound. However, in patients with severe aortic or pulmonary stenosis, the murmur may extend beyond the 1st component of the 2nd sound, thus obscuring it. *Pansystolic* or *holosystolic murmurs* begin almost simultaneously with the 1st heart sound and continue throughout systole, on occasion becoming gradually decrescendo. It is helpful to remember that after closure of the atrioventricular valves (the 1st heart sound), a brief period occurs during which ventricular pressure increases but the semilunar valves remain closed (isovolumic contraction; see Fig. 415–3). Thus, pansystolic murmurs (heard during both isovolumic contraction and the ejection phases of systole) cannot be caused by flow across the semilunar valves because these valves are closed during isovolumic contraction. Pansystolic murmurs are therefore related to blood exiting the contracting ventricle via either an abnormal opening (a ventricular septal defect) or atrioventricular (mitral or tricuspid) valve insufficiency. Systolic ejection murmurs usually imply increased flow or stenosis across one of the ventricular outflow tracts (aortic or pulmonic). In infants with rapid heart rates, it is often difficult to distinguish between ejection and pansystolic murmurs. If a clear and distinct 1st heart sound can be appreciated, the murmur is most likely ejection in nature.

Task Force on Blood Pressure Control in Children. National Heart, Lung, and Blood Institute, Bethesda, Maryland. *Pediatrics* 1987;79:1. Copyright American Academy of Pediatrics 1987.)

A **continuous murmur** is a systolic murmur that continues or “spills” into diastole and indicates continuous flow, such as in the presence of a patent ductus arteriosus or other aortopulmonary communication. This murmur should be differentiated from a **to-and-fro murmur**, which indicates that the systolic component of the murmur ends at or before the 2nd sound and the diastolic murmur begins after semilunar valve closure (e.g., aortic or pulmonary stenosis combined with insufficiency). A late systolic murmur begins well beyond the 1st heart sound and continues until the end of systole. Such murmurs may be heard after a midsystolic click in patients with mitral valve prolapse and insufficiency.

Several types of **diastolic murmurs** (graded I–IV) can be identified. A **decrescendo diastolic murmur** is a blowing murmur along the left sternal border that begins with S_2 and diminishes toward mid-diastole. When high-pitched, this murmur is associated with aortic valve insufficiency or pulmonary insufficiency related to pulmonary hypertension. When low-pitched, this murmur is associated with pulmonary valve insufficiency in the absence of pulmonary hypertension. A low-pitched decrescendo diastolic murmur is typically noted after surgical repair of the pulmonary outflow tract in defects such as tetralogy of Fallot or in patients with absent pulmonary valves. A **rumbling mid-diastolic murmur** at the left middle and lower sternal border may be due to increased blood flow across the tricuspid valve, such as occurs with an atrial septal defect or, less often, because of actual stenosis of this valve. When this murmur is heard at the apex, it is caused by increased flow across the mitral valve, such as occurs with large left-to-right shunts at the ventricular level (ventricular septal defects), at the great vessel level (patent ductus arteriosus, aortopulmonary shunts), or with increased flow because of mitral insufficiency. When an apical diastolic rumbling murmur is longer and is accentuated at the end of diastole (presystolic), it usually indicates anatomic mitral valve stenosis.

The absence of a precordial murmur does not rule out significant congenital or acquired heart disease. Congenital heart defects, some of which are ductal dependent, may not demonstrate a murmur if the ductus arteriosus closes. These lesions include pulmonary or tricuspid valve atresia and transposition of the great arteries. Murmurs may seem insignificant in patients with severe aortic stenosis, atrial septal defects, anomalous pulmonary venous return, atrioventricular septal defects, coarctation of the aorta, or anomalous insertion of a coronary artery. Careful attention to other components of the physical examination (growth failure, cyanosis,

peripheral pulses, precordial impulse, heart sounds) increases the index of suspicion of congenital heart defects in these cases. In contrast, loud murmurs may be present in the absence of structural heart disease, for example, in patients with a large noncardiac arteriovenous malformation, myocarditis, severe anemia, or hypertension.

Many murmurs are not associated with significant hemodynamic abnormalities. These murmurs are referred to as functional, normal, insignificant, or innocent (the preferred term).

Figure 415-3 Idealized diagram of the temporal events of a cardiac cycle.

During routine random auscultation, more than 30% of children may have an *innocent murmur* at one time in their lives; this percentage increases when auscultation is carried out under nonbasal circumstances (high cardiac output because of fever, infection, anxiety). The most common innocent murmur is a medium-pitched, **vibratory** or **"musical,"** relatively short systolic ejection murmur, which is heard best along the left lower and midsternal border and has no significant radiation to the apex, base, or back. It is heard most frequently in children between 3 and 7 yr of age. The intensity of the murmur often changes with respiration and position and may be attenuated in the sitting or prone position. Innocent pulmonic murmurs are also common in children and adolescents and originate from normal turbulence during ejection into the pulmonary artery. They are higher pitched, blowing, brief early systolic murmurs of grade I–II in intensity and are best detected in the 2nd left parasternal space with the patient in the supine position. Features suggestive of heart disease include murmurs that are pansystolic, grade III or higher, harsh, located at the left upper sternal border, and associated with an early or midsystolic click or an abnormal 2nd heart sound.

A **venous hum** is another example of a common innocent murmur heard during childhood. Such hums are produced by turbulence of blood in the jugular venous system; they have no pathologic significance and may be heard in the neck or anterior portion of the upper part of the chest. A venous hum consists of a soft humming sound heard in both systole and diastole; it can be exaggerated or made to disappear by varying the position of the head, or it can be decreased by lightly compressing the jugular venous system in the neck. These simple maneuvers are sufficient to differentiate a venous hum from the murmurs produced by organic cardiovascular disease, particularly a patent ductus arteriosus.

The lack of significance of an innocent murmur should be discussed with the child's parents. It is important to offer complete reassurance because lingering doubts about the importance of a cardiac murmur may have profound effects on child-rearing practices, most often in the form of overprotectiveness. An underlying fear that a cardiac abnormality is present may negatively affect a child's self-image and subtly influence personality development. The physician should explain that an innocent murmur is simply a "noise" and does not indicate the presence of a significant cardiac defect. When asked, "Will it go away?" the best response is to state that because the murmur has no meaning, it does not matter whether it "goes away" or not. Parents should be warned that the intensity of the murmur might increase during febrile illnesses. However, with growth, innocent murmurs are less well heard and often disappear completely. At times, additional studies may be indicated to rule out a congenital heart defect, but "routine" electrocardiographic, chest roentgenographic, and echocardiographic examinations should be avoided in well children with innocent murmurs.

Chapter 416 - Laboratory Evaluation

416.1 Radiologic Assessment

The chest roentgenogram may provide information about cardiac size and shape, pulmonary blood flow (vascularity), pulmonary edema, and associated lung and thoracic anomalies that may be associated with congenital syndromes (skeletal dysplasias, extra or deficient number of ribs, abnormal vertebrae, previous cardiac surgery). Variations are due to differences in body build, the phase of respiration or the cardiac cycle, abnormalities of the thoracic cage, position of the diaphragm, or pulmonary disease.

The most frequently used measurement of cardiac size is the maximal width of the cardiac shadow in a posteroanterior chest

---

film taken during midinspiration. A vertical line is drawn down the middle of the sternal shadow, and perpendicular lines are drawn from the sternal line to the extreme right and left borders of the heart; the sum of the lengths of these lines is the *maximal cardiac width*. The *maximal chest width* is obtained by drawing a horizontal line between the right and left inner borders of the rib cage at the level of the top of the right diaphragm. When the maximal cardiac width is more than half the maximal chest width (**cardiothoracic ratio** >50%), the heart is usually enlarged. Cardiac size should be evaluated only when the film is taken during inspiration with the patient in an upright position. A diagnosis of “cardiac enlargement” on expiratory or prone films is a common cause of unnecessary referrals and laboratory studies.

The cardiothoracic ratio is a less useful index of cardiac enlargement in infants than in older children because the horizontal position of the heart may increase the ratio to more than 50% in the absence of true enlargement. Furthermore, the thymus may overlap not only the base of the heart but also virtually the entire mediastinum, thus obscuring the true cardiac silhouette.

A lateral chest roentgenogram may be helpful in infants as well as in older children with pectus excavatum or other conditions that result in a narrow anteroposterior chest dimension. In these situations, the heart may appear small in the lateral view and suggest that the apparent enlargement in the posteroanterior projection was due to either the thymic image (anterior mediastinum only) or flattening of the cardiac chambers as a result of a structural chest abnormality.

In the posteroanterior view, the left border of the cardiac shadow consists of three convex shadows produced, from above downward, by the aortic knob, the main and left pulmonary arteries, and the left ventricle (Fig. 416–1). In cases of moderate to marked left atrial enlargement, the atrium may project between the pulmonary artery and the left ventricle. The outflow tract of the right ventricle does not contribute to the shadows formed by the left border of the heart. The aortic knob is not as easily seen in infants and children as in adults. However, the side of the aortic arch (left or right) can often be inferred as being opposite the side of the midline from which the air-filled trachea is visualized. This observation is important because a right-sided aortic arch is often present in cyanotic congenital heart disease, particularly the tetralogy of Fallot. Three structures contribute to the right border of the cardiac silhouette: from above downward they are the superior vena cava, the ascending aorta, and the right atrium.

Enlargement of cardiac chambers or major arteries and veins results in prominence of the areas in which these structures are normally outlined on the chest roentgenogram. In contrast, the electrocardiogram (ECG) is a more sensitive and accurate index of ventricular *hypertrophy*.

It is also important to assess the degree of *pulmonary vascularity*. Angiocardiographic studies have shown that the hilar shadows are mainly vascular. Pulmonary overcirculation is usually associated with left-to-right shunt lesions, whereas pulmonary undercirculation is associated with obstruction of the outflow tract of the right ventricle.

The esophagus is closely related to the great vessels, and a barium esophagogram can help delineate these structures in the initial evaluation of suspected vascular rings. However, echocardiographic examination best defines the morphologic features of intracardiac chambers, and CT and MRI best define extracardiac vascular morphology.

416.2 Electrocardiography

DEVELOPMENTAL CHANGES

The marked changes that occur in cardiac physiology and chamber dominance during the perinatal transition (see Chapter 414) are reflected in the evolution of the ECG during

Figure 416.2-1 Idealized diagrams showing normal position of the cardiac chambers and great blood vessels. P.A. = posteroanterior; SVC = superior vena cava; RA = right atrium; RV = right ventricle; PA = pulmonary artery; RPA = right pulmonary artery; LPA = left pulmonary artery; LA = left atrium; LV = left ventricle; IVC = inferior vena cava. (Adapted and redrawn from Dotter and Steinberg: *Radiology* 1949;53:513.)

the neonatal period. Because vascular resistance in the pulmonary and systemic circulations is nearly equal in a term fetus, the intrauterine work of the heart results in an equal mass of both the right and left ventricles. After birth, systemic vascular resistance rises when the placental circulation is eliminated, and pulmonary vascular

resistance falls when the lungs expand. These changes are reflected in the ECG as the right ventricular wall begins to thin.

The ECG demonstrates these anatomic and hemodynamic features principally by changes in QRS and T-wave morphologic features. It is recommended that a 13-lead ECG be performed in pediatric patients, including either lead V_3 R or V_4 R, which are important in the evaluation of right ventricular hypertrophy. On occasion, lead V_1 is positioned too far leftward to reflect right ventricular forces accurately. This problem is present particularly in premature infants, in whom the electrocardiographic electrode gel may produce contact among all the precordial leads.

During the 1st days of life, *right axis deviation*, large R waves, and upright T waves in the right precordial leads (V_3 R or V_4 R and V_1) are the norm (Fig. 416–2). As pulmonary vascular resistance decreases in the 1st few days after birth, the right precordial T waves become negative. In the great majority of instances, this change occurs within the 1st 48?hr of life. Upright T waves that persist in leads V_3 R, V_4 R, or V_1 beyond 1 wk of life are an abnormal finding indicating right ventricular hypertrophy or strain, even in the absence of QRS voltage criteria. The T wave in V_1 should never be positive before 6 yr of age and may remain negative into adolescence. This finding represents one of the most important, yet subtle differences between pediatric and

Figure 416.2-2 Electrocardiogram in a normal neonate younger than 24?hr of age. Note the dominant R wave and upright T waves in leads V_3 R and V_1 (V_3 R paper speed = 50?mm/sec).

adult ECGs and is a common source of error when adult cardiologists interpret pediatric ECGs.

In a newborn, the mean QRS frontal-plane axis normally lies in the range of +110 to +180 degrees. The right-sided chest leads reveal a larger positive (R) than negative (S) wave and may do so for months or years because the right ventricle remains relatively thick throughout infancy. Left-sided leads (V_5 and V_6) also reflect *right-sided dominance* in the early neonatal period, when the R:S ratio in these leads may be less than 1. A dominant R wave reflecting left ventricular forces quickly becomes evident within the 1st few days of life (Fig. 416–3). Over the years, the QRS axis gradually shifts leftward, and the right ventricular forces slowly regress. Leads V_1 , V_3 R, and V_4 R display a prominent R wave until 6 mo–8 yr of age. Most children have an R:S ratio greater than 1 in lead V_4 R until they are 4 yr of age. The T waves are inverted in leads V_4 R, V_1 , V_2 , and V_3 during infancy and may remain so into the middle of the 2nd decade of life and beyond. The processes of right ventricular thinning and left ventricular growth are best reflected in the QRS-T pattern over the right precordial leads. The diagnosis of right or left ventricular hypertrophy in a pediatric patient can be made only with an understanding of the normal developmental physiology of these chambers at various ages until adulthood is reached. As the left ventricle becomes dominant, the ECG evolves to the characteristic pattern of older children (Fig. 416–4) and adults (Fig. 416–5).

Figure 416.2-3 Electrocardiogram of a normal infant. Note the tall R and small S waves in V_4 R and V_1 and the inverted T wave in these leads. A dominant R wave is also present in V_6 .

Figure 416.2-4 Electrocardiogram of a normal child. Note the relatively tall R waves and inversion of the T waves in V_4 R and V_1 .

Ventricular hypertrophy may result in increased voltage in the R and S waves in the chest leads. The height of these deflections is governed by the proximity of the specific electrode to the surface of the heart; by the sequence of electrical activation through the ventricles, which can result in variable degrees of cancellation of forces; and by hypertrophy of the myocardium. Because the chest wall in infants and children, as well as in adolescents, may be relatively thin, the diagnosis of ventricular hypertrophy should not be based on voltage changes alone.

The diagnosis of pathologic right ventricular hypertrophy is difficult in the 1st wk of life because physiologic right ventricular hypertrophy is a normal finding. Serial tracings are often necessary to determine whether marked right axis deviation and potentially abnormal right precordial forces or T waves, or both, will persist beyond the neonatal period (Fig. 416–6). In contrast, an adult electrocardiographic pattern seen in a neonate suggests left ventricular enlargement (see Fig. 416–5). The exception is a premature infant, who may display a more “mature” ECG than a full-term infant (Fig. 416–7) as a result of lower pulmonary vascular resistance secondary to underdevelopment of the medial muscular layer of the pulmonary arterioles. Some premature infants display a pattern of generalized low voltage across the precordium.

The ECG should always be evaluated systematically to avoid the possibility of overlooking a minor, but important abnormality. One approach is to begin with an assessment of rate and rhythm, followed by a calculation of the mean frontal-plane QRS axis, measurements of segment intervals, assessment of voltages, and finally, assessment of ST and T-wave abnormalities.

Figure 416.2-5 Normal adult electrocardiogram. Note the dominant S wave in lead V_1 . This pattern in an infant would indicate the presence of left ventricular hypertrophy.

Figure 416.2-6 Electrocardiogram of an infant with right ventricular hypertrophy (tetralogy of Fallot). Note the tall R waves in the right precordium and deep S waves in V_6 . The positive T waves in V_4 R and V_1 are also characteristic of right ventricular hypertrophy.

RATE AND RHYTHM

A brief rhythm strip should be examined to assess whether a P wave always precedes each QRS complex. The P-wave axis should then be estimated as an indication of whether the rhythm is originating from the sinus node. If the atria are situated normally in the chest, the P wave should be upright in leads I and aVF and inverted in lead aVR. With atrial inversion (situs inversus), the P wave may be inverted in lead I. Inverted P waves in leads II and aVF are seen in nodal or junctional rhythms regardless of atrial position. The absence of P waves indicates a rhythm originating more distally in the conduction system. In this case, the morphologic features of the QRS complexes are important in differentiating a junctional (usually a narrow QRS complex) from a ventricular (usually a wide QRS complex) rhythm.

P WAVES

Tall (>2.5?mm), narrow, and spiked P waves are indicative of right atrial enlargement and are seen in congenital pulmonary stenosis, Ebstein anomaly of the tricuspid valve, tricuspid atresia, and sometimes cor pulmonale. These abnormal waves are most obvious in leads II, V_3 R, and V_1 (Fig. 416–8*A*). Similar waves are sometimes seen in thyrotoxicosis. Broad P waves, commonly bifid and sometimes biphasic, are indicative of left atrial enlargement (see Fig. 416–8*B*). They are seen in some patients with large left-to-right shunts (ventricular septal defect [VSD], patent ductus arteriosus [PDA]) and with severe mitral stenosis or regurgitation. Flat P waves may be encountered in hyperkalemia.

Figure 416.2-7 Electrocardiogram of a premature infant (weight 2?kg and age 5 wk at the time of the tracing). The cardiovascular system was clinically normal. Left ventricular dominance is manifested by R-wave progression across the chest, similar to tracings obtained from older children. Compare with the tracing from a normal full-term infant (Fig. 416–3).

Figure 416.2-8 Atrial enlargement. *A*, Peaked narrow P waves characteristic of right atrial enlargement. *B*, Wide bifid **M**-shaped P waves typical of left atrial enlargement.

QRS COMPLEX

Right Ventricular Hypertrophy.

For the most accurate assessment of ventricular hypertrophy, pediatric ECGs should include the right precordial lead V_3 R or V_4 R, or both. The diagnosis of right ventricular hypertrophy depends on demonstration of the following changes (see Fig. 416–6): (1) a qR pattern in the right ventricular surface leads; (2) a positive T wave in leads V_3 R–V_4 R and V_1 –V_3 between the ages of 6 days and 6 yr; (3) a monophasic R wave in V_3 R, V_4 R, or V_1 ; (4) an rsR' pattern in the right precordial leads with the 2nd R wave taller than the initial one; (5) age-corrected increased voltage of the R wave in leads V_3 R–V_4 R or the S wave in leads V_6 –V_7 , or both; (6) marked right axis deviation (>120 degrees in patients beyond the newborn period); (7) complete reversal of the normal adult precordial RS pattern; and (8) right atrial enlargement. At least two of these changes should be present to support a diagnosis of right ventricular hypertrophy.

Abnormal ventricular loading can be characterized as either systolic (as a result of obstruction of the right ventricular outflow tract, as in pulmonic stenosis) or diastolic (as a result of increased volume load, as in atrial septal defects [ASDs]). These two types of abnormal loads result in distinct electrocardiographic patterns. The *systolic overload pattern* is characterized by tall, pure R waves in the right precordial leads. In older children, the T waves in these leads are initially upright and later become inverted. In infants and children younger than 6 yr, the T waves in V_3 R–V_4 R and V_1 are abnormally upright. The *diastolic overload pattern* is characterized by an rsR' pattern (Fig. 416–9) and a slightly increased QRS duration (minor right ventricular conduction delay). Patients with mild to moderate pulmonary stenosis may also exhibit an rsR pattern in the right precordial leads.

Left Ventricular Hypertrophy.

The following features indicate the presence of left ventricular hypertrophy (Fig. 416–10): (1) depression of the ST segments and inversion of the T waves in the left precordial leads (V_5 , V_6 , and V_7), known as a left ventricular strain pattern—these findings suggest the presence of a severe lesion; (2) a deep Q wave in the left precordial leads; and (3) increased voltage of the S wave in V_3 R and V_1 or the R wave in V_6 –V_7 , or both. It is important to emphasize that evaluation of left ventricular hypertrophy should not be based on voltage criteria alone. The concepts of systolic and diastolic overload, though not always consistent, are also useful in evaluating left ventricular enlargement. Severe *systolic overload* of the left ventricle is suggested by straightening of the ST segments and inverted T waves over the left precordial leads; *diastolic overload* may result in tall R waves, a large Q wave, and normal T waves over the left precordium. Finally, an infant with an ECG that would be considered “normal” for an older child may in fact have left ventricular hypertrophy.

Figure 416.2-9 Electrocardiogram showing right ventricular conduction delay characterized by an rsR' pattern in V_1 and a deep S wave in V_6 (V_3 R paper speed = 50?mm/sec).

Bundle Branch Block.

A complete right bundle branch block may be congenital or may be acquired after surgery for congenital heart disease, especially when a right ventriculotomy has been performed as in repair of the tetralogy of Fallot. Congenital left bundle branch block is rare; this pattern is occasionally seen with cardiomyopathy. A bundle branch block pattern may be indicative of a bypass tract associated with one of the pre-excitation syndromes (see Chapter 428).

P-R AND Q-T INTERVALS

The duration of the P-R interval shortens with increasing heart rate; thus, assessment of this interval should be based on age- and rate-corrected nomograms. A long P-R interval is diagnostic of a 1st-degree heart block, the cause of which may be congenital, postoperative, inflammatory (myocarditis, pericarditis, rheumatic fever), or pharmacologic (digitalis).

The duration of the Q-T interval varies with the cardiac rate; a corrected Q-T interval (Q-Tc) can be calculated by dividing the measured Q-T interval by the square root of the preceding R-R interval. A normal Q-Tc should be less than 0.45. It is often

Figure 416.2-10 Electrocardiogram showing left ventricular hypertrophy in a 12-yr-old child with aortic stenosis. Note the deep S wave in V_1 –V_3 and tall R in V_5 . In addition, T-wave inversion is present in leads II, III, aVF, and V_6 .

Figure 416.2-11 Electrocardiogram in hypokalemia (serum potassium, 2.7?mEq/L; serum calcium, 4.8?mEq/L at the time of the tracing). Note the prolongation of electrical systole as evidenced by a widened TU wave, as well as depression of the ST segment in V_4 R, V_1 , and V_6 .

lengthened with hypokalemia and hypocalcemia; in the former instance, a U wave may be noted at the end of the T wave (Fig. 416–11). A congenitally prolonged Q-T interval (Fig. 416–12) may also be seen in children with one of the long Q-T syndromes. These patients are at high risk for ventricular arrhythmias, including a form of ventricular tachycardia known as *torsades de pointes*, and sudden death (see Chapter 428.6).

ST SEGMENT AND T-WAVE ABNORMALITIES

A slight elevation of the ST segment may occur in normal teenagers and is attributed to early repolarization of the heart. In pericarditis, irritation of the epicardium may cause *elevation of the ST segment* followed by abnormal T-wave inversion as healing progresses. Administration of digitalis is sometimes associated with sagging of the ST segment and abnormal inversion of the T wave.

Depression of the ST segment may also occur in any condition that produces myocardial damage or ischemia, including severe anemia, carbon monoxide poisoning, aberrant origin of the left coronary artery from the pulmonary artery, glycogen storage disease of the heart, myocardial tumors, and mucopolysaccharidoses. An aberrant origin of the left coronary artery from the pulmonary artery may lead to changes indistinguishable from those of acute myocardial infarction in adults. Similar changes may occur in patients with other rare abnormalities of the coronary arteries and in those with cardiomyopathy, even in the presence of normal coronary arteries. These patterns are often misread in young infants because of the unfamiliarity of pediatricians with this “infarct” pattern, and thus a high index of suspicion must be maintained in infants with symptoms compatible with coronary ischemia.

T-wave inversion may occur in myocarditis and pericarditis, or it may be a sign of either right or left ventricular hypertrophy and strain. Hypothyroidism may produce flat or inverted T waves in association with generalized low voltage. In hyperkalemia, the T waves are commonly of high voltage and are tent-shaped (Fig. 416–13).

Figure 416.2-12 Prolonged Q-T interval in a patient with long Q-T syndrome.

Figure 416.2-13 Electrocardiogram in hyperkalemia (serum potassium, 6.5?mEq/L; serum calcium, 5.1?mEq/L). Note the tall, tent-shaped T waves, especially in leads I, II, and V_6 .

416.3 Hematologic Data

In acyanotic infants with large left-to-right shunts, the onset of heart failure often coincides with the nadir of the normal *physiologic anemia* of infancy. Increasing the hematocrit in these patients to greater than 40% can decrease shunt volume and result in an improvement in symptoms; however, this form of treatment is reserved for infants who are not otherwise surgical candidates (extremely premature infants or those with exceedingly complex congenital heart disease for whom only palliative surgery is possible). In these select infants, regular evaluation of the hematocrit and booster transfusions when appropriate may be helpful in improving growth.

Polycythemia is frequently noted in cyanotic patients with right-to-left shunts. Patients with severe polycythemia are in a delicate balance between the risks of intravascular thrombosis and a bleeding diathesis. The most frequent abnormalities include accelerated fibrinolysis, thrombocytopenia, abnormal clot retraction, hypofibrinogenemia, prolonged prothrombin time, and prolonged partial thromboplastin time. The preparation of cyanotic, polycythemic patients for elective surgery, such as dental extraction, includes evaluation and treatment of abnormal coagulation.

Because of the high viscosity of polycythemic blood (hematocrit >65%), patients with cyanotic congenital heart disease are at risk for the development of vascular thromboses, especially of cerebral veins. Dehydration increases the risk of thrombosis, and thus adequate fluid intake must be maintained during hot weather or intercurrent gastrointestinal illnesses. Diuretics should be used with caution in these patients and may need to be decreased if fluid intake is a concern. Polycythemic infants with concomitant iron deficiency are at even greater risk for cerebrovascular accidents, probably because of the decreased deformability of microcytic red blood cells. Iron therapy produces improvement, but surgical treatment of the cardiac anomaly is the best therapy.

Severely cyanotic patients should have periodic determinations of hemoglobin and hematocrit. Increasing polycythemia, often associated with headache, fatigue, dyspnea, or a combination of these conditions, is one indication for palliative or corrective surgical intervention. In cyanotic patients with inoperable conditions, phlebotomy may be required to treat individuals whose hematocrit has risen to the 65–70% level, usually when the polycythemia is associated with symptoms such as headache. This procedure is not without risk, especially in patients with an extreme

elevation in pulmonary vascular resistance. Because these patients do not tolerate wide fluctuations in circulating blood volume, blood should be replaced with fresh frozen plasma or albumin. Whether routine phlebotomy should be performed in polycythemic patients who are asymptomatic is controversial.

416.4 Echocardiography

Echocardiography dramatically reduces the requirement for invasive studies such as cardiac catheterization. The echocardiographic examination can be used to evaluate cardiac structure in congenital heart lesions, estimate intracardiac pressures and gradients across stenotic valves and vessels, quantitate cardiac contractile function (both systolic and diastolic), determine the direction of flow across a defect, examine the integrity of the coronary arteries, and detect the presence of vegetations from endocarditis, as well as the presence of pericardial fluid, cardiac tumors, and chamber thrombi. Echocardiography may also be used to assist in the performance of pericardiocentesis, balloon atrial septostomy (see Chapter 424.2), and endocardial biopsy and in the placement of flow-directed pulmonary artery (Swan-Ganz) monitoring catheters. *Transesophageal echocardiography* is used to monitor ventricular function in patients during difficult surgical procedures and can provide an immediate assessment of the results of surgical repair of congenital heart lesions. *Fetal echocardiography* can detect the presence of many congenital heart lesions, often as early as 17–19 wk of gestation, and is especially valuable in evaluating fetal cardiac arrhythmias. A complete echocardiographic examination usually entails a combination of M-mode and two-dimensional imaging, as well as pulsed, continuous, and color Doppler flow studies.

M-MODE ECHOCARDIOGRAPHY

M-mode echocardiography displays a one-dimensional slice of cardiac structure varying over time. It is used mostly for the measurement of cardiac dimensions (wall thickness and chamber size) and cardiac function (fractional shortening, wall thickening). M-mode echocardiography is also useful for assessing the motion of intracardiac structures (opening and closing of valves, movement of free walls and septa) and the anatomy of valves (Fig. 416–14). The most frequently used index of cardiac function in children is *percent fractional shortening*, which is calculated as (LVED – LVES)/LVED, where LVED is left ventricular (LV) dimension at end-diastole and LVES is LV dimension at end-systole. Normal fractional shortening is 28–40%. Other M-mode indices of cardiac function include the mean velocity of fiber shortening (mean V_{CF}), systolic time intervals (LVPEP = LV pre-ejection period, LVET = LV ejection time), and isovolemic contraction time. More sophisticated indices of cardiac function can be derived noninvasively with the assistance of echocardiography (pressure-volume relationship, end-systolic wall stress-strain relationship); however, their accuracy is limited when compared with similar measurements in the catheterization laboratory.

TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Two-dimensional echocardiography provides a real-time image of cardiac structures. With two-dimensional echocardiography, the contracting heart is imaged in several standard views (subxiphoid, Fig. 416–15 ; parasagittal, Fig. 416–16 ; parasternal, Fig. 416–17 ; and suprasternal, Fig. 416–18) that emphasize specific structures.

Two-dimensional echocardiography has replaced cardiac angiography for the preoperative diagnosis of many, but not all congenital heart lesions, and it exceeds angiography in several areas, for example, in imaging the atrioventricular valves and their chordal attachments. When information from the cardiac examination is not consistent with the echocardiogram, cardiac catheterization is an important tool to confirm the

Figure 416.4-14 M-mode echocardiogram. *A*, Diagram of a sagittal section of a heart showing the structures traversed by the echo beam as it is moved superiorly to positions (1), (2), and (3). AMC = anterior mitral cusp; APM = anterior papillary muscle; Dec. aorta = descending aorta; LA = left atrium; LV = left ventricle; PMC = posterior mitral cusp; PPM = posterior papillary muscle; RV = right ventricle. B, Echocardiogram from transducer position (1); this view is the best one for measuring cardiac dimensions and fractional shortening. RVED = RV dimension at end-diastole; LVED = LV dimension at end-diastole (Dd); Ds = LV dimension in systole. CW = chest wall. Fractional shortening is calculated as (LVED – LVES)/LVED.

anatomic diagnosis and evaluate the degree of physiologic derangement.

DOPPLER ECHOCARDIOGRAPHY

Doppler echocardiography displays blood flow in cardiac chambers and vascular channels based on the change in frequency imparted to a sound wave by the movement of erythrocytes. In *pulsed Doppler* and *continuous wave Doppler*, the speed and direction of blood flow in the line of the echo beam change the transducer's reference frequency. This frequency change can be translated into volumetric flow (L/min) data for estimating systemic or pulmonary blood flow and into pressure (mm Hg) data for estimating gradients across the semilunar or atrioventricular valves or across septal defects or vascular communications such as shunts (Fig. 416–19). *Color Doppler* permits highly accurate

Figure 416.4-15 Subxiphoid normal echocardiographic view. The anterior angulation shows the mitral valve and the left ventricular inflow tract. Note the pulmonary veins connecting with the left atrium. LA = left atrium; LPV = left pulmonary vein; RPV = right pulmonary vein; LV = left ventricle; p-s = posterior-superior; r = right; RA = right atrium. (From Sanders SP: Echocardiography. In Long WA [editor]: *Fetal and Neonatal Cardiology*. Philadelphia, WB Saunders, 1990.)

assessment of the presence and direction of intracardiac shunts and allows identification of small or multiple left-to-right or right-to-left shunts. The severity of valvular insufficiency is also more accurately evaluated with color Doppler.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography is an extremely sensitive imaging technique that produces a clearer view of smaller lesions such as vegetations in endocarditis. It is useful in visualizing posteriorly located structures such as the atria, aortic root, and atrioventricular valves. Transesophageal echocardiography has been extremely

useful as an intraoperative technique for

Figure 416.4-16 Right parasagittal normal echocardiographic plane view showing the junction of the inferior and superior venae cavae with the right atrium. a = anterior; IVC = inferior vena cava; LA = left atrium; RA = right atrium; RPA = right pulmonary artery; s = superior; SVC = superior vena cava. (From Sanders SP: Echocardiography. In Long WA [editor]: *Fetal and Neonatal Cardiology*. Philadelphia, WB Saunders, 1990.)

monitoring cardiac function during both cardiac and noncardiac surgery and for screening for residual cardiac defects after cardiopulmonary bypass. This technique has been especially helpful in evaluating the degree of residual regurgitation after repair of atrioventricular septal defects and in searching for small muscular VSDs that may have been missed during the closure of larger defects.

FETAL ECHOCARDIOGRAPHY

Fetal echocardiography can be used to evaluate cardiac structures or disturbances in cardiac rhythm. Obstetricians often detect gross abnormalities in cardiac structure on routine obstetric ultrasonography or may refer the patient because of unexplained hydrops fetalis. Fetal echocardiography may be capable of diagnosing congenital heart lesions as early as 17–19 wk of gestation; however, accuracy at this early stage is limited. Serial fetal echocardiograms have also demonstrated the importance of flow disturbance in the pathogenesis of

Figure 416.4-18 Suprasternal notch normal echocardiographic view showing the pulmonary veins connecting with the left atrium. Ao = aorta; a-s = anterior-superior; LA = left atrium; LPV = left pulmonary vein; MPA = main pulmonary artery; RPV = right pulmonary vein; r = right; SVC = superior vena cava. Figure 416.4-19 Patent ductus arteriosus. *A*, Doppler flow in the proximal descending aorta of a normal infant demonstrating normal antegrade systolic and diastolic flow. *B*, The Doppler flow configuration in an infant with patent ductus arteriosus reveals antegrade systolic, but retrograde diastolic flow (*arrows*).

congenital heart disease; such studies can show the intrauterine progression of a moderate lesion, such as aortic stenosis, into a more severe lesion, such as hypoplastic left heart syndrome. M-mode echocardiography can diagnose rhythm disturbances in the fetus and can determine the success of antiarrhythmic therapy administered to the mother. A screening fetal echocardiogram is recommended for patients with a previous child or 1st-degree relative with congenital heart disease, for patients who are at higher risk of having a child with cardiac disease (e.g., insulin-dependent diabetics, patients with exposure to teratogenic drugs during early pregnancy), and in any fetus in which a chromosomal abnormality is suspected or confirmed.

VENTRICULAR FUNCTION

Sophisticated M-mode and two-dimensional echocardiographic methods of assessing left ventricular systolic and diastolic function (e.g., end-systolic wall stress and dobutamine stress echocardiography) have proved useful in the serial assessment of patients at risk for the development of ventricular dysfunction. Such patients include those receiving anthracycline drugs for cancer chemotherapy, patients at risk for iron overload, and patients being monitored for rejection or coronary artery disease after heart transplantation.

416.5 Exercise Testing

The normal cardiorespiratory system adapts to the extensive demands of exercise with a several-fold increase in oxygen consumption and cardiac output. Because of the large reserve capacity for exercise, significant abnormalities in cardiovascular performance may be present without symptoms at rest or during ordinary activities. When patients are evaluated in a resting state, significant abnormalities in cardiac function may not be appreciated, or if detected, their implications for quality of life may not be recognized. Permission for children with cardiovascular disease to participate in various forms of physical activity is frequently based on totally subjective criteria. Exercise testing plays an important role in evaluating symptoms, quantitating

---

the severity of cardiac abnormalities, and assisting in the management of these patients, including prescribing a rational physical activity schedule.

In older children, exercise studies are generally performed on a graded treadmill apparatus with timed intervals of increasing grade and speed. In younger children, exercise studies are performed on a bicycle ergometer. Many laboratories now have the capacity to measure cardiac output and pulmonary function noninvasively during exercise.

As a child grows, the capacity for work is enhanced with increased body size and skeletal muscle mass. All indices of cardiopulmonary function do not increase in a uniform manner, however. A major response to exercise is an increase in cardiac output, principally achieved through an increase in heart rate, but stroke volume, systemic venous return, and pulse pressure are also increased. Systemic vascular resistance is greatly decreased as the blood vessels in working muscle dilate in response to increasing metabolic demands. As the child becomes older and larger, the response of the heart rate to exercise remains prominent, but cardiac output increases because of growing cardiac volume capacity and hence stroke volume. Responses to dynamic exercise are not dependent solely on age. For any given

body surface area, boys have a larger stroke volume than size-matched girls do. This increase is also mediated by posture. Augmentation of stroke volume with upright, dynamic exercise is facilitated by the pumping action of working muscles, which overcomes the static effect of gravity and increases systemic venous return.

Dynamic exercise testing defines not only endurance and exercise capacity but also the effect of such exercise on myocardial blood flow and cardiac rhythm. Significant ST segment depression reflects abnormalities in myocardial perfusion, for example, the subendocardial ischemia that commonly occurs during exercise in children with hypertrophied left ventricles. The exercise ECG is considered abnormal if the ST segment depression is greater than 2?mm and extends for at least 0.06?sec after the J point (onset of the ST segment) in conjunction with a horizontal-, upward-, or downward-sloping ST segment. Provocation of rhythm disturbances during an exercise study is an important method of evaluating selected patients with known or suspected rhythm disorders. The effect of pharmacologic management can also be tested in this manner.

416.6 MRI, Electron Beam CT, and Radionuclide Studies

MRI is helpful in the diagnosis and management of patients with congenital heart disease. It produces tomographic images of the heart in any projection (Fig. 416–20), with excellent contrast resolution of fat, myocardium, and lung, as well as moving blood from blood vessel walls. MRI has been particularly useful in evaluating areas that are less well visualized by echocardiography, such as distal branch pulmonary artery anatomy and anomalies in systemic and pulmonary venous return.

Magnetic resonance angiography allows the acquisition of images in several tomographic planes. Within each plane, images are obtained at different phases of the cardiac cycle. Thus, when displayed in a dynamic “cine” format, changes in wall thickening, chamber volume, and valve function can be displayed and analyzed. Blood flow velocity and blood flow volume can be approximated. Phosphorus *magnetic resonance spectroscopy* provides a means of demonstrating relative concentrations of high-energy metabolites (e.g., adenosine triphosphate, adenosine diphosphate, inorganic phosphate, and phosphocreatine) within regions of the working myocardium.

Electron beam CT (EBCT) scanning is used to perform rapid, respiration-gated cardiac imaging in children with a resolution

Figure 416.6-20 Sagittal normal MRI. AO = aorta; BV = brachiocephalic vein; LA = left atrium; LCA = left coronary artery; LV = left ventricle; MPA = main pulmonary artery; RV = right ventricle. (From Bisset GS III: Cardiac and great vessel anatomy. In El-Khoury GY, Bergman RA, Montgomery WJ [editors]: *Sectional Anatomy by MRI/CT*. New York, Churchill Livingstone, 1990.)

down to 0.5?mm. Three-dimensional reconstruction of EBCT images (Fig. 416–21) is especially useful in evaluating branch pulmonary arteries, anomalies in systemic and pulmonary venous return, and great vessel anomalies such as coarctation of the aorta.

Radionuclide angiography may be used to detect and quantify shunts and to analyze the distribution of blood flow to each lung. This technique is particularly useful in quantifying the volume of blood flow distribution between the two lungs in patients with abnormalities of the pulmonary vascular tree, after a shunt operation (Blalock-Taussig or Glenn), or to quantify the success of balloon angioplasty and intravascular stenting procedures. *Gated blood pool scanning* can be used to calculate hemodynamic measurements, quantify valvular regurgitation, and detect regional wall motion abnormalities. *Thallium imaging* can be performed to evaluate cardiac muscle perfusion. These methods can be used at the bedside of seriously ill children and can be performed serially, with minimal discomfort and low radiation exposure.

416.7 Cardiac Catheterization

Cardiac catheterization is an important tool in the diagnosis of congenital heart disease. During catheterization, blood samples are obtained for measuring oxygen saturation and calculating shunt volumes, pressures are measured for calculating gradients and valve areas, and contrast is injected to delineate structures. Major indications for cardiac catheterization include (1) presurgical evaluation of cardiac anatomy or shunt size, or both, in children with congenital cardiac lesions when echocardiographic

Figure 416.7-21 Three-dimensional reconstruction of electron beam CT images from a neonate with severe coarctation of the aorta. The patent ductus arteriosus can be seen toward the left leading from the main pulmonary artery to the descending aorta. The tortuous and narrow coarctated segment is just to the right of the ductus. The transverse aorta is hypoplastic as well. MPA = main pulmonary artery; AAo = ascending aorta; DAo = descending aorta; RAA = right atrial appendage; RPA = right pulmonary artery; LA = left atrium. (Image courtesy of Dr. Paul Pitlick, Stanford University, Stanford, CA.)

evaluation is incomplete; (2) evaluation of pulmonary vascular resistance and its response to vasodilators or oxygen; (3) follow-up after surgical repair or palliation of complex congenital heart lesions; (4) myocardial biopsy for the diagnosis of cardiomyopathy or screening for cardiac rejection after transplantation; (5) interventional cardiac catheterization; and (6) electrophysiologic study or transcatheter ablation, or both (see Chapter 428).

Although the risks are low, cardiac catheterization involves potential complications for the patient and should not be used without an opportunity for benefit. Echocardiography, MRI, EBCT, or radionuclide studies may be used in lieu of multiple cardiac catheterizations in individual patients who require careful monitoring of their hemodynamic status. The number of postoperative catheterizations has increased with the advent of palliative surgical procedures to repair complex congenital heart lesions. Interventional cardiac catheterization has replaced surgical repair in many cases (e.g., pulmonary or aortic valve stenosis, re-coarctation of the aorta, closure of small PDAs), is competing with it in others (ASDs, muscular VSD, large PDA), and in still others is used as an adjunct to complex surgical repairs (branch pulmonary artery stenosis, closure of a fenestrated Fontan palliation [see Chapter 423.4]).

Cardiac catheterization should be performed with the patient in as close to a basal state as possible. Conscious sedation is routinely used for most of these studies; however, if general anesthesia is required, careful choice of an anesthetic agent is warranted to avoid depression of cardiovascular function and subsequent distortion of the calculations of cardiac output, pulmonary and systemic vascular resistance, and shunt ratios.

Cardiac catheterization in critically ill infants with congenital heart disease should be performed in a center where a pediatric cardiovascular surgical team is available in the event that an operation is required immediately afterward. The complication rate of cardiac catheterization and angiography is greatest in critically ill infants; they must be studied in a thermally neutral environment and treated quickly for hypothermia, hypoglycemia, acidosis, or excessive blood loss.

Catheterization usually includes both the right and left sides of the heart. The catheter is passed into the heart under fluoroscopic guidance through a percutaneous entry point in a femoral vein, although occasionally, jugular access is used. In infants and in a large number of older children, the left side of the heart can be accessed by passing the catheter across a patent foramen ovale to the left atrium and left ventricle. If the foramen is closed, the left side of the heart can also be catheterized by passing the catheter retrograde via a percutaneous entry site into the femoral artery. The catheter can be manipulated through abnormal intracardiac defects (ASDs, VSDs). Complete hemodynamics can be calculated (Box 416–1), including cardiac output, intracardiac left-to-right and right-to-left shunts, and systemic and pulmonary vascular resistance. Normal circulatory dynamics is depicted in Figure 416–22 .

THERMODILUTION MEASUREMENT OF CARDIAC OUTPUT

The *thermodilution method* for measuring cardiac output is performed with a flow-directed, thermistor-tipped, pulmonary artery (Swan-Ganz) catheter. A known change in the heat content of the blood is induced at one point in the circulation (usually the right atrium or inferior vena cava), and the resultant change in temperature is detected at a point downstream (usually the pulmonary artery). The injectate is generally room temperature

Box 416.7-1. Normal Values and Formulas for Determination of Hemodynamics in Cardiac Catheterization

1. Cardiac index: 3.0–5.0 L/min/m^2
2. Arteriovenous oxygen difference: 4.5 ± 0.7 mL/dL
3. Oxygen consumption: 140–160 mL/m^2 /min
4. Arterial oxygen saturation: 94–100%
5. Pulmonary arteriolar resistance: 50–150 dyn sec cm^{-5} (1 U = 80 dynes)
6. Cardiac output (Qs) mL/min = systemic flow =
7. Cardiac index: cardiac output (L/min)/m^2 of body surface area
8. Pulmonary artery flow (Qp) =

   If a pulmonary venous sample is not available, it is assumed to be saturated to 95% of capacity
9. Effective pulmonary artery flow (Qep) =
10. Total left-to-right shunt: pulmonary artery flow minus effective pulmonary artery flow
11. Total right-to-left shunt: systemic flow minus effective pulmonary artery flow
12. Pulmonary arteriolar resistance:

where

R
: pulmonary arteriolar resistance (resistance units)

PA
: mean pulmonary artery pressure in mm Hg

PC
: mean pulmonary “capillary” pressure in mm Hg

Qp
: pulmonary flow in L/min/m^2

saline. This method is used to measure cardiac output in the catheterization laboratory in patients without shunts. Monitoring cardiac output by the thermodilution method can also be useful in managing critically ill infants and children in an intensive care setting after cardiac surgery or in the presence of shock. In this case, a triple-lumen catheter is used for both cardiac output determination and measurement of pulmonary artery and pulmonary capillary wedge pressure.

ANGIOCARDIOGRAPHY

The major blood vessels and individual cardiac chambers may be visualized by selective angiocardiography, or the injection of contrast material into specific chambers or great vessels. This method allows identification of structural abnormalities without interference from the superimposed shadows of normal chambers. *Fluoroscopy* is used to visualize the catheter as it passes through the various heart chambers. After the cardiac catheter is properly placed in the chamber to be studied, a small amount of contrast medium is injected with a power injector, and cineangiograms are exposed at rates ranging from 15 to 90 frames/sec. *Biplane cineangiocardiography* allows detailed evaluation of specific cardiac chambers and blood vessels in two planes simultaneously with the injection of a single bolus of contrast material. This technique is standard in pediatric cardiac catheterization laboratories and allows one to minimize the volume of contrast material used, which is safer for the patient. Various angled views (e.g., left anterior oblique, cranial angulation) are used to display specific anatomic features best in individual lesions. Digital imaging is beginning to replace standard roentgenographic film for both diagnostic and archival purposes.

Rapid injection of contrast medium under pressure into the circulation is not without risk, and each injection should be carefully planned. Contrast agents consist of hypertonic solutions, with some containing organic iodides, which can cause complications, including nausea, a generalized burning sensation, central nervous system symptoms, and allergic reactions. Intramyocardial injection is generally avoided by careful placement of the catheter before injection. Hypertonicity of the contrast medium may result in transient myocardial depression and a drop in blood pressure, followed soon afterward by tachycardia, an increase in cardiac output, and a shift of interstitial fluid into the circulation. This shift can transiently increase the symptoms of heart failure in critically ill patients.

INTERVENTIONAL CATHETERIZATION

Nonsurgical treatment of certain cardiac defects is routine with interventional cardiac catheterization. Interventional techniques include balloon dilatation of stenotic valves and arteries, embolization of abnormal vascular connections, and catheter closure of both intracardiac and extracardiac defects. The procedure most often used is *balloon valvuloplasty*. A special catheter with a sausage-shaped balloon at the distal end is passed through an obstructed valve. Rapid filling of the balloon with a mixture of contrast material and saline solution results in tearing of the stenotic valve tissue, usually at the site of inappropriately fused raphe. Valvular pulmonary stenosis can be treated successfully by balloon angioplasty, and in most patients angioplasty has replaced surgical repair as the initial procedure of choice. The clinical results of this procedure are similar to those obtained by open heart surgery, but without the need for sternotomy or prolonged hospitalization. Balloon valvuloplasty for aortic stenosis has also yielded excellent results, although as with surgery, aortic stenosis often recurs as the child grows and multiple procedures may thus be required. One complication of both valvuloplasty and surgery is the creation of valvular insufficiency. This complication has more serious implications when it occurs on the aortic vs the pulmonary side of the circulation because regurgitation is less well tolerated at systemic arterial pressures.

Balloon angioplasty is the procedure of choice for patients with re-stenosis of coarctation of the aorta after earlier surgery. It is controversial whether angioplasty is the best procedure for native (unoperated) coarctation of the aorta because of reports of later aneurysm formation. The risk of angioplasty and valvuloplasty procedures on the left side of the heart is higher in younger patients, especially infants less than 1 yr of age, because of complications at the site of femoral artery catheterization. Low-profile catheters have significantly reduced, though not totally eliminated these complications. Other applications of the balloon angioplasty technique include amelioration of mitral stenosis, dilatation of surgical conduits (Mustard or Senning atrial baffles), relief of branch pulmonary artery narrowing, dilatation of venous obstructions, and the long-used balloon atrial septostomy (Rashkind procedure) for transposition of the great arteries (see Chapter 424.2).

Interventional cardiac catheterization techniques using *metal coils* have been developed for obliteration of arteriovenous shunts and pulmonary collateral vessels, which may be detrimental after surgical repair of pulmonary atresia and VSD. Coils have been used to close small and medium-sized PDAs with excellent results. In patients with branch pulmonary artery stenoses, the previously mixed results with balloon angioplasty

alone have been enhanced with the use of *intravascular stents* delivered over a balloon catheter and expanded within the vessel lumen. Once placed, they can often be dilated to successively greater sizes as the patient grows. Placement of stents in small infants and children remains problematic because of problems associated with subsequent growth.

The use of catheter-introduced devices to close congenital cardiac defects has produced good results. Currently, several devices (clamshell, Helex, button) are undergoing clinical trials for closure of small to moderate-sized ASDs. Umbrella or bag devices may also be introduced to close a large PDA not amenable to coil closure. High-risk patients undergoing the Fontan operation (see Chapter 423.4) often have a small fenestration created in the baffle between the right and left sides

of the circulation to serve as a "popoff valve" for high right-sided pressure in the early surgical period. Patients with these "fenestrated Fontans" are ideal candidates for subsequent closure with a catheter-delivered device. Patients with apical muscular VSDs, especially when associated with other cardiac defects, may be candidates for catheter closure with a clamshell-type device because of the higher risk of standard surgery. ASD closure devices are approved by the Food and Drug Administration for general use.

Section 3 - *Congenital Heart Disease*

Daniel Bernstein

Chapter 417 - Epidemiology and Genetic Basis of Congenital Heart Disease

Prevalence.

Congenital heart disease occurs in 0.5–0.8% of live births. The incidence is higher in stillborns (3–4%), abortuses (10–25%), and premature infants (about 2% excluding patent ductus arteriosus [PDA]). This overall incidence does not include mitral valve prolapse, PDA of preterm infants, and bicuspid aortic valves (present in 1–2% of adults). Congenital cardiac defects have a wide spectrum of severity in infants: about 2–3 in 1,000 newborn infants will be symptomatic with heart disease in the 1st yr of life. The diagnosis is established by 1 wk of age in 40–50% of patients with congenital heart disease and by 1 mo of age in 50–60% of patients. With advances in both palliative and corrective surgery in the last 20 yr, the number of children with congenital heart disease surviving to adulthood has increased dramatically. Despite these advances, congenital heart disease remains the leading cause of death in children with congenital malformations. Table 417–1 summarizes the relative frequency of the most common congenital cardiac lesions.

Most congenital defects are well tolerated in the fetus because of the parallel nature of the fetal circulation. Even the most

TABLE 417-1 -- **Relative Frequency of Major Congenital Heart Lesions[*]**

Lesion	% of All Lesions
Ventricular septal defect	25–30

Atrial septal defect (secundum)	6–8
Patent ductus arteriosus	6–8
Coarctation of aorta	5–7
Tetralogy of Fallot	5–7
Pulmonary valve stenosis	5–7
Aortic valve stenosis	4–7
d-Transposition of great arteries	3–5
Hypoplastic left ventricle	1–3
Hypoplastic right ventricle	1–3
Truncus arteriosus	1–2
Total anomalous pulmonary venous return	1–2
Tricuspid atresia	1–2
Single ventricle	1–2
Double-outlet right ventricle	1–2
Others	5–10

** Excluding patent ductus arteriosus in preterm neonates, bicuspid aortic valve, physiologic peripheral pulmonic stenosis, and mitral valve prolapse.*

severe cardiac defects (hypoplastic left heart syndrome) can usually be well compensated for by the fetal circulation. In this example, the entire fetal cardiac output would be ejected by the right ventricle via the ductus arteriosus into both the descending and ascending aortae (the latter filling in a retrograde fashion). It is only after birth when the fetal pathways (ductus arteriosus and foramen ovale) are closed that the full hemodynamic impact of an anatomic abnormality becomes apparent (see Chapter 414). One notable exception is the case of severe regurgitant lesions, most commonly of the tricuspid valve. In these lesions (Ebstein anomaly [see *Chapter 423.7*]), the parallel fetal circulation cannot compensate for the volume load imposed on the right side of the heart. In utero heart failure, often with fetal pleural and pericardial effusions, and generalized ascites (nonimmune hydrops fetalis) may occur.

Although the most significant transitions in circulation occur in the immediate perinatal period, the circulation continues to undergo changes after birth, and these later changes may also have a hemodynamic impact on cardiac lesions and their apparent incidence. As pulmonary vascular resistance falls over the 1st several weeks of life, left-to-right shunting through intracardiac defects increases and symptoms become more apparent. Thus, in patients with a ventricular septal defect (VSD), heart failure is often manifested between 1 and 3 mo of age (see Chapter 419.6). The severity of various defects can also change dramatically with growth; some VSDs may become smaller and even close as the child ages. Alternatively, stenosis of the aortic or pulmonary valve, which may be mild in the newborn period, may become worse if valve orifice growth does not keep pace with patient growth (see Chapter 420.5). The physician should always be alert for associated congenital malformations, which can adversely affect the patient's prognosis (see Table 415–2).

Etiology.

The cause of most congenital heart defects is unknown, but rapid progress is being made in identifying the genetic basis of many congenital heart lesions. Most cases of congenital heart disease were thought to be multifactorial and result from a combination of genetic predisposition and environmental stimulus. A small percentage of congenital heart lesions were related to chromosomal abnormalities, in particular, trisomy 21, 13, and 18 and Turner syndrome: heart disease is found in more than 90% of patients with trisomy 18, 50% of patients with trisomy 21, and 40% of those with Turner syndrome. Other genetic factors were suspected to play a role in congenital heart disease; for example, certain types of VSDs (supracristal) are more common in Asian children. The risk of recurrence of congenital heart disease increases if a 1st-degree relative (parent or sibling) is affected.

A growing list of congenital heart lesions have been associated with specific chromosomal abnormalities, and several have even been linked to specific gene defects. Fluorescent in situ hybridization analysis allows clinicians rapid screening of suspected cases once a specific chromosomal abnormality has been identified.

A well-characterized genetic cause of congenital heart disease is the deletion of a large region of chromosome 22q11, known as the DiGeorge critical region. The estimated prevalence of 22q11 deletions is 1 in 4,000 live births. Cardiac lesions associated with 22q11 deletions are most often seen in association with either the DiGeorge syndrome or the Shprintzen (velocardiofacial) syndrome. The acronym CATCH 22 has been used to summarize the major components of these syndromes (*c*ardiac defects, *a*bnormal facies, *t*hymic aplasia, *c*left palate, and *h*ypocalcemia). The specific cardiac anomalies are conotruncal defects (tetralogy of Fallot, truncus arteriosus, double-outlet right ventricle, subarterial VSD) and branchial arch defects (coarctation of the aorta, interrupted aortic arch, right aortic arch). Congenital airway anomalies such as tracheomalacia and bronchomalacia are sometimes present. Although the risk of recurrence is extremely low in the absence of a parental 22q11 deletion, it is 50% if one of the parents carries the deletion.

Other structural heart lesions that have been associated with specific chromosomal abnormalities include familial secundum atrial septal defect associated with heart block (the transcription factor NKX2.5 on chromosome 5q35), Alagille syndrome (Jagged1 on chromosome 20p12), and Williams syndrome (elastin on chromosome 7q11). A compilation of known genetic causes of congenital heart disease is presented in Table 417–2 .

The familial cardiomyopathies also require genetic evaluation. Hypertrophic cardiomyopathy is linked to missense mutations in the ß-myosin heavy chain gene on chromosome 14, the cardiac troponin T gene on chromosome 1q3, a-tropomyosin on chromosome 15q2, and cardiac myosin-binding protein C on chromosome 11q11. X-linked cardiomyopathies have been linked to the dystrophin gene on Xp21, also the cause of the muscular dystrophies (see Table 417–2). The genetic basis of

heritable arrhythmias, most notably the long Q-T syndromes, has been linked to mutations of genes coding for subunits of cardiac potassium and sodium channels (see Table 417–2).

Two to 4% of cases of congenital heart disease are associated with known environmental or adverse maternal conditions and teratogenic influences, including maternal diabetes mellitus, phenylketonuria, or systemic lupus erythematosus; congenital rubella syndrome; and maternal ingestion of drugs (lithium, ethanol, warfarin, thalidomide, antimetabolites, anticonvulsant agents) (see Table 415–2). Associated noncardiac malformations noted in identifiable syndromes may be seen in as many as 25% of patients with congenital heart disease (see Table 415–1).

Gender differences in the occurrence of specific cardiac lesions have been identified. Transposition of the great arteries and left-sided obstructive lesions are slightly more common in boys (approximately 65%), whereas atrial septal defect, VSD, PDA, and pulmonic stenosis are more common in girls. No racial differences in the occurrence of congenital heart lesions as a whole have been noted; for specific lesions such as transposition of the great arteries, a higher occurrence is seen in white infants.

Genetic Counseling.

Parents who have a child with congenital heart disease require genetic counseling regarding the probability of a cardiac malformation occurring in subsequent children (see Chapter 72). With the exception of syndromes known to be due to mutation of a single gene, most congenital heart disease is still relegated to a multifactorial inheritance pattern, which should result in a low risk of recurrence. The

TABLE 417-2 -- Genetics of Congenital Heart Disease

Cardiovascular Disease	Chromosomal Location	Gene
Structural Heart Defects		
CATCH 22 (DiGeorge syndrome, velocardiofacial syndrome)	22q11	Not known
Familial ASD with heart block	5q35	Nkx2.5
Alagille syndrome (bile duct hypoplasia, right-sided cardiac lesions)	20p12	Jagged1
Holt-Oram syndrome (limb defects, ASD)	12q2	TBX5
Trisomy 21 (AV septal defect)	21q22	Not known

ASD = atrial septal defect; AV = atrioventricular;TAPVR = total anomalous pulmonary venous return; PS = pulmonic stenosis; AS = aortic stenosis; PDA = patent ductus arteriosus; RV = right ventricular.

incidence of congenital heart disease in the normal population is approximately 0.8%, and this incidence increases to 2–6% for a 2nd pregnancy after the birth of a child with congenital heart disease or if a parent is affected. This recurrence risk is highly dependent on the type of lesion in the 1st child. When two 1st-degree relatives have congenital heart disease, the risk for a subsequent child may reach 20–30%. When a 2nd child is found to have congenital heart disease, it will tend to be of a similar class as the lesion in their 1st-degree relative (e.g., conotruncal lesions, left-sided obstructive lesions, atrioventricular septation defects). The degree of severity may be variable, as is the presence of associated defects. Certain cardiac lesions, for example, left-sided obstructive lesions, may be associated with a much higher rate of recurrence because of the presence of mild and clinically silent defects in other family members, such as a bicuspid aortic valve. Consultation with a knowledgeable genetic counselor is the most reliable way of providing the family with up-to-date information regarding the risk of recurrence.

Fetal echocardiography improves the rate of detection of congenital heart lesions in high-risk patients (see Chapter 85.5). The resolution and accuracy of fetal echocardiography are not perfect, and families should be counseled that a normal fetal echocardiogram does not guarantee the absence of congenital heart disease. Congenital heart lesions may also evolve during the course of the pregnancy; for example, moderate aortic stenosis with a normal-sized left ventricle at 18 wk of gestation may evolve into aortic atresia with a hypoplastic left ventricle by 34 wk because of decreased flow through the atria, ventricle, and aorta during the latter half of gestation.

The major factor in determining whether a woman with congenital heart disease, either unoperated or operated, will be able to carry a fetus to term is the mother's cardiovascular status. In the presence of a mild congenital heart defect or after successful repair of a more severe lesion, normal childbearing is likely. However, in a woman with poor cardiac function, the increased hemodynamic burden imposed by pregnancy may result in a significantly increased risk to both the mother and fetus. The incidence of spontaneous abortion in the presence of severe congenital heart disease is high, especially when the mother is cyanotic. The maternal risk in these situations is also high. It is important to discuss various methods of birth control with young women who have repaired or palliated congenital heart lesions. Antibiotic prophylaxis against endocarditis is also indicated at the time of delivery.

Chapter 418 - Evaluation of the Infant or Child with Congenital Heart Disease

The initial evaluation for suspected congenital heart disease involves a systematic approach with three major components. First, congenital cardiac defects can be divided into two major groups based on the presence or absence of cyanosis, which can be determined by physical examination aided by pulse oximetry. Second, these two groups can be further subdivided according to whether the chest radiograph shows evidence of increased, normal, or decreased pulmonary vascular markings. Finally, the electrocardiogram can be used to determine whether right, left, or biventricular hypertrophy exists. The character of the heart sounds and the presence and character of any murmurs further narrow the differential diagnosis. The final diagnosis is then confirmed by echocardiography or cardiac catheterization, or by both.

ACYANOTIC CONGENITAL HEART LESIONS

Acyanotic congenital heart lesions can be classified according to the predominant physiologic load that they place on the heart. Although many congenital heart lesions induce more than one physiologic disturbance, it is helpful to focus on the primary load abnormality for purposes of classification. The most common lesions are those that produce a *volume load*, and the most common of these are left-to-right shunt lesions. Atrioventricular (AV) valve regurgitation and some of the cardiomyopathies are other causes of increased volume load. The second major class of lesions causes an increase in *pressure load*, most commonly secondary to ventricular outflow obstruction (e.g., pulmonic or aortic valve stenosis) or narrowing of one of the great vessels (e.g., coarctation of the aorta). The chest radiograph and electrocardiogram are useful tools for differentiating between these major classes of volume and pressure overload lesions.

Lesions Resulting in Increased Volume Load.

The most common lesions in this group are those that cause left-to-right shunting (see Chapter 419): atrial septal defect, ventricular septal defect (VSD), AV septal defects (AV canal), and patent ductus arteriosus. The pathophysiologic common denominator in this group is communication between the systemic and pulmonary sides of the circulation, which results in shunting of fully oxygenated blood back into the lungs. This shunt can be quantitated by calculating the ratio of pulmonary to systemic blood flow, or Qp:Qs. Thus, a 2:1 shunt implies twice the normal pulmonary blood flow.

The direction and magnitude of the shunt across such a communication depend on the size of the defect and the relative pulmonary and systemic pressure and vascular resistance. These factors are dynamic and may change dramatically with age: intracardiac defects may grow smaller with time; pulmonary vascular resistance, which is high in the immediate newborn period, decreases to normal adult levels by several weeks of life; and chronic exposure of the pulmonary circulation to high pressure and blood flow results in a gradual increase in pulmonary vascular resistance (Eisenmenger physiology, see Chapter 426.2). Thus, a lesion such as a large VSD may be associated with little shunting and few symptoms during the initial weeks of life. When pulmonary vascular resistance declines over the next several weeks, the volume of the left-to-right shunt increases, and symptoms begin to appear.

The increased volume of blood in the lungs decreases pulmonary compliance and increases the work of breathing. Fluid leaks into the interstitial space and alveoli and causes pulmonary edema. The infant acquires the symptoms we refer to as heart failure, such as tachypnea, chest retractions, nasal flaring, and wheezing. The term *heart failure* is a misnomer, however; total left ventricular output is actually several times greater than normal, although much of this output is ineffective because it returns directly to the lungs. To maintain this high level of left ventricular output, heart rate and stroke volume are increased, mediated by an increase in sympathetic nervous system activity. The increase in circulating catecholamines, combined with the increased work of breathing, results in an elevation in total body oxygen consumption, often beyond the oxygen transport ability of the circulation. Such oxygen consumption leads to the additional symptoms of sweating, irritability, and failure to thrive. Remodeling of the heart occurs, with predominantly dilatation and a lesser degree of hypertrophy. If left untreated, pulmonary vascular resistance eventually begins to rise, and by several years of age the shunt volume will decrease and eventually reverse to right to left (Eisenmenger physiology, Chapter 426.2).

Additional lesions that impose a volume load on the heart include regurgitant lesions (see Chapter 421) and the cardiomyopathies (see Chapter 431). Regurgitation through the AV valves is most commonly encountered in patients with partial or complete AV septal defects (atrioseptal defects, AV canal). In these lesions, the combination of a left-to-right shunt with AV valve regurgitation increases the volume load on the heart and leads to more severe symptoms. Isolated regurgitation through the tricuspid valve is seen in Ebstein anomaly (see Chapter 423.7). Regurgitation involving one of the semilunar valves is usually also associated with stenosis; however, aortic regurgitation may be encountered in patients with a VSD directly under the aortic valve (supracristal VSD).

In contrast to left-to-right shunts, in which intrinsic cardiac muscle function is generally either normal or increased, heart muscle function is decreased in the cardiomyopathies. Cardiomyopathies may affect systolic contractility or diastolic relaxation, or both. Decreased cardiac function results in increased atrial and ventricular filling pressure, and pulmonary edema occurs secondary to increased capillary pressure. The major causes of cardiomyopathy in infants and children include viral myocarditis, metabolic disorders, and genetic defects (see Chapter 431).

Lesions Resulting in Increased Pressure Load.

The pathophysiologic common denominator of these lesions is an obstruction to normal blood flow. The most frequent are obstructions to ventricular outflow: valvular pulmonic stenosis, valvular aortic stenosis, and coarctation of the aorta (see Chapter 420). Less common are obstruction to ventricular inflow: tricuspid or mitral stenosis and cor triatriatum. Ventricular outflow obstruction can occur at the valve, below the valve (e.g., double-chambered right ventricle, subaortic membrane), or above it (e.g., branch pulmonary stenosis or supravalvular aortic stenosis). Unless the obstruction is severe, cardiac output will be maintained and the clinical symptoms of heart failure will be either subtle or absent. This compensation predominantly involves an increase in cardiac wall thickness (hypertrophy), but in later stages it also involves dilatation.

The clinical picture is different when obstruction to outflow is severe, which is usually encountered in the immediate newborn period. The infant may become critically ill within several hours of birth. Severe pulmonic stenosis in the newborn period *(critical pulmonic stenosis)* results in signs of right-sided heart failure (hepatomegaly, peripheral edema), as well as cyanosis from right-to-left shunting across the foramen ovale. Severe aortic stenosis in the newborn period *(critical aortic stenosis)* is characterized by signs of left-sided heart failure (pulmonary edema, poor perfusion) and right-sided failure (hepatomegaly, peripheral edema), and it may progress rapidly to total circulatory collapse. In older children, severe pulmonic stenosis leads to symptoms of right-sided heart failure, but not to cyanosis unless a pathway persists for right-to-left shunting (e.g., patency of the foramen ovale).

Coarctation of the aorta in older children and adolescents is usually manifested as upper body hypertension and diminished pulses in the lower extremities. In the immediate newborn period, however, the occurrence of coarctation may be delayed because of the presence of a patent ductus arteriosus. In these patients, the open aortic end of the ductus may serve as a conduit for blood flow to partially bypass the obstruction. These infants then become symptomatic, often dramatically, when the ductus finally closes.

CYANOTIC CONGENITAL HEART LESIONS

This group of congenital heart lesions can also be further divided according to pathophysiology: whether pulmonary blood flow is decreased (tetralogy of Fallot, pulmonary atresia with an intact septum, tricuspid atresia, total anomalous pulmonary venous return with obstruction) or increased (transposition of the great vessels, single ventricle, truncus arteriosus, total anomalous pulmonary venous return without obstruction). The chest radiograph is a valuable tool for initial differentiation between these two categories.

Cyanotic Lesions with Decreased Pulmonary Blood Flow.

These lesions must include both an obstruction to pulmonary blood flow (at the tricuspid valve or right ventricular or pulmonary valve level) and a pathway by which

systemic venous blood can shunt from right to left and enter the systemic circulation (via a patent foramen ovale, atrial septal defect, or VSD). Common lesions in this group include tricuspid atresia, tetralogy of Fallot, and various forms of single ventricle with pulmonary stenosis (see Chapter 423). In these lesions, the degree of cyanosis depends on the degree of obstruction to pulmonary blood flow. If the obstruction is mild, cyanosis may be absent at rest. These patients may have hypercyanotic ("tet") spells during conditions of stress. In contrast, if the obstruction is severe, pulmonary blood flow may be dependent on patency of the ductus arteriosus. When the ductus closes during the 1st few days of life, the neonate experiences profound hypoxemia and shock.

Cyanotic Lesions with Increased Pulmonary Blood Flow.

This group of lesions is not associated with obstruction to pulmonary blood flow. Cyanosis is caused by either abnormal ventricular-arterial connections or total mixing of systemic venous and pulmonary venous blood within the heart (see Chapter 424). Transposition of the great vessels is the most common of the former group of lesions. In this condition, the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle. Systemic venous blood returning to the right atrium is pumped directly back to the body, and oxygenated blood returning from the lungs to the left atrium is pumped back into the lungs. The persistence of fetal pathways (foramen ovale and ductus arteriosus) allows for a small degree of mixing in the immediate newborn period; when the ductus begins to close, these infants become extremely cyanotic.

Total mixing lesions include cardiac defects with a common atrium or ventricle, total anomalous pulmonary venous return, and truncus arteriosus (see Chapter 424). In this group, deoxygenated systemic venous blood and oxygenated pulmonary venous blood mix completely in the heart, and as a result, oxygen saturation is equal in the pulmonary artery and aorta. If pulmonary blood flow is not obstructed, these infants have a combination of cyanosis and heart failure. In contrast, if pulmonary stenosis is present, these infants have cyanosis alone, similar to patients with the tetralogy of Fallot.

Chapter 419 - Acyanotic Congenital Heart Disease: The Left-to-Right Shunt Lesions

419.1 Atrial Septal Defect

Atrial septal defects (ASDs) can occur in any portion of the atrial septum (secundum, primum, or sinus venosus), depending on which embryonic septal structure has failed to develop normally (see Chapter 413). Less commonly, the atrial septum may be nearly absent, with the creation of a functional single atrium. Isolated secundum ASDs account for approximately 7% of congenital heart defects. The majority of cases of ASD are sporadic; however, autosomal dominant inheritance does occur as part of the Holt-Oram syndrome (hypoplastic or absent radii, 1st-degree heart block, ASD).

An isolated valve-incompetent patent foramen ovale (PFO) is a common echocardiographic finding during infancy. It is usually of no hemodynamic significance and is not considered an ASD; however, a PFO may play an important role if other structural heart defects are present. If another cardiac anomaly is causing increased right atrial pressure (e.g., pulmonary stenosis or atresia, tricuspid valve abnormalities, right ventricular dysfunction), venous blood may shunt across the PFO into the left atrium with resultant cyanosis. Because of the anatomic structure of the PFO, left-to-right shunting is unusual outside the immediate newborn period. In the presence of a large volume load or a hypertensive left atrium (e.g., secondary to mitral

stenosis), the foramen ovale may be sufficiently dilated to result in a significant atrial left-to-right shunt. A valve-competent but probe-patent foramen ovale may be present in 15–30% of adults. An isolated PFO does not require surgical treatment, although it may be a risk for paradoxical (right to left) systemic embolization.

419.2 Ostium Secundum Defect

An ostium secundum defect in the region of the fossa ovalis is the most common form of ASD and is associated with structurally normal atrioventricular (AV) valves. Mitral valve prolapse has been described in association with this defect but is rarely an important clinical consideration. Secundum ASDs may be single or multiple (fenestrated atrial septum), and openings 2?cm or larger in diameter are common in symptomatic older children. Large defects may extend inferiorly toward the inferior vena cava and ostium of the coronary sinus, superiorly toward the superior vena cava, or posteriorly. Females outnumber males 3:1 in incidence. Partial anomalous pulmonary venous return, most commonly of the right upper pulmonary vein, may be an associated lesion.

Pathophysiology.

The degree of left-to-right shunting is dependent on the size of the defect, the relative compliance of the right and left ventricles, and the relative vascular resistance in the pulmonary and systemic circulations. In large defects, a considerable shunt of oxygenated blood flows from the left to the right atrium (Fig. 419–1). This blood is added to the usual venous return to the right atrium and is pumped by the right ventricle to the lungs. With large defects, the ratio of pulmonary to systemic blood flow (Qp:Qs) is usually between 2:1 and 4:1. The paucity of symptoms in infants with ASDs is related to the structure of the right ventricle in early life when its muscular wall is thick and less compliant, thus limiting the left-to-right shunt. As the infant becomes older and pulmonary vascular resistance drops, the right ventricular wall becomes thinner and the left-to-right shunt across the ASD increases. The large blood flow through the right side of the heart results in enlargement of the right atrium and ventricle and dilatation of the pulmonary artery. The left atrium may be enlarged; however, the left ventricle and aorta are normal in size. Despite the large pulmonary blood flow, pulmonary arterial pressure is usually normal because of the absence of a high-pressure communication between the pulmonary and systemic circulations. Pulmonary vascular resistance remains low throughout childhood, although it may begin to increase in adulthood and may eventually result in reversal of the shunt and clinical cyanosis.

Clinical Manifestations.

A child with an ostium secundum defect is most often asymptomatic; the lesion may be discovered inadvertently during physical examination. Even an extremely large secundum ASD rarely produces clinically evident heart failure in childhood. In younger children, subtle failure to thrive may be present; in older children, varying degrees of exercise intolerance may be noted. Often, the degree of limitation may go unnoticed by the family until after surgical repair, when the child's growth or activity level increases markedly.

The physical findings of an ASD are usually characteristic but fairly subtle and require careful examination of the heart, with special attention to the heart sounds. Examination of the chest may reveal a mild left precordial bulge. A right ventricular systolic lift is generally palpable at the left sternal border. A loud 1st heart sound and sometimes a pulmonic ejection click can be heard. In most patients, the 2nd heart sound is characteristically widely split and fixed in its splitting in all phases of respiration. Normally, the duration of right ventricular ejection varies with respiration, with inspiration increasing right ventricular volume and delaying closure of the pulmonary valve. With an ASD,

Figure 419.2-1 Physiology of atrial septal defect (ASD). Circled numbers represent oxygen saturation values. The numbers next to the arrows represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 2:1.

Desaturated blood enters the right atrium from the vena cavae at a volume of 3?L/min/m^2 and mixes with an additional 3?L of fully saturated blood shunting left to right across the ASD; the result is an increase in oxygen saturation in the right atrium. Six liters of blood flows through the tricuspid valve and causes a mid-diastolic flow rumble. Oxygen saturation may be slightly higher in the right ventricle because of incomplete mixing at the atrial level. The full 6?L flows across the right ventricular outflow tract and causes a systolic ejection flow murmur. Six liters returns to the left atrium, with 3?L shunting left to right across the defect and 3?L crossing the mitral valve to be ejected by the left ventricle into the ascending aorta (normal cardiac output).

right ventricular diastolic volume is constantly increased and the ejection time is prolonged throughout all phases of respiration. A systolic ejection murmur is heard; it is medium pitched, without harsh qualities, seldom accompanied by a thrill, and best heard at the left middle and upper sternal border. It is produced by the increased flow across the right ventricular outflow tract into the pulmonary artery, not by low-pressure flow across the ASD. A short, rumbling mid-diastolic murmur produced by the increased volume of blood flow across the tricuspid valve is often audible at the lower left sternal border. This finding, which may be subtle and is heard best with the bell of the stethoscope, usually indicates a Qp:Qs ratio of at least 2:1.

Diagnosis.

The *chest roentgenogram* shows varying degrees of enlargement of the right ventricle and atrium, depending on the size of the shunt. The pulmonary artery is large, and pulmonary vascularity is increased. These signs vary and may not be conspicuous in mild cases. Cardiac enlargement is often best appreciated on the lateral view because the right ventricle protrudes anteriorly as its volume increases. The *electrocardiogram* shows volume overload of the right ventricle; the QRS axis may be normal or exhibit right axis deviation, and a minor right ventricular conduction delay (rsR' pattern in the right precordial leads) may be present.

The *echocardiogram* shows findings characteristic of right ventricular volume overload, including an increased right ventricular end-diastolic dimension and flattening and abnormal motion of the ventricular septum. A normal septum moves posteriorly during systole and anteriorly during diastole. With right ventricular

overload and normal pulmonary vascular resistance, septal motion is reversed—that is, anterior movement in systole—or the motion may be intermediate so that the septum remains straight. The location and size of the atrial defect are readily appreciated by two-dimensional scanning, with a characteristic brightening of the echo image seen at the edge of the defect (T-artifact). The shunt is confirmed by pulsed and color flow Doppler. Patients with the classic features of a hemodynamically significant ASD on physical examination and chest radiography in whom echocardiographic identification of an isolated secundum ASD is made need not be catheterized before surgical closure, with the exception of an older patient, in whom pulmonary vascular resistance may be a concern.

If the diagnosis is suspected, shunt size cannot be reliably determined by noninvasive tests; if pulmonary vascular disease is suspected, *cardiac catheterization* confirms the presence of the defect and allows measurement of the shunt ratio and pulmonary pressure. The oxygen content of blood from the right atrium will be much higher than that from the superior vena cava. This feature is not specifically diagnostic because it may occur with partial anomalous pulmonary venous return to the right atrium, with a ventricular septal defect (VSD) in the presence of tricuspid insufficiency, with AV septal defects associated with left ventricular–to–right atrial shunts, and with aorta-to–right atrial communications (e.g., ruptured sinus of Valsalva aneurysm). Pressure in the right side of the heart is usually normal, but small to moderate pressure gradients (<25?mm Hg) may be measured across the right ventricular outflow tract because of functional stenosis related to excessive blood flow. Pulmonary vascular resistance is almost always normal. The shunt is variable and depends on the size of the defect, but it may be of considerable volume (as high as 20?L/min/m^2). *Cineangiography*, performed with the catheter through the defect and in the right upper pulmonary vein, demonstrates the defect and the location of the right upper pulmonary venous drainage. Alternatively, pulmonary angiography demonstrates the defect on the levophase (return of contrast to the left side of the heart after passing through the lungs).

Prognosis and Complications.

ASDs detected in term infants may close spontaneously. Secundum ASDs are well tolerated during childhood, and symptoms do not usually appear until the 3rd decade or later. Pulmonary hypertension, atrial dysrhythmias, tricuspid or mitral insufficiency, and heart failure are late manifestations; these symptoms may initially appear during the increased volume load of pregnancy. Infective endocarditis is extremely rare, and antibiotic prophylaxis for isolated secundum ASDs is not recommended. Postoperative complications such as late heart failure and atrial fibrillation are more common in patients who undergo surgery after 20 yr of age.

Secundum ASDs are usually isolated, although they may be associated with partial anomalous pulmonary venous return, pulmonary valvular stenosis, VSD, pulmonary artery branch stenosis, and persistent left superior vena cava, as well as mitral valve prolapse and insufficiency. Secundum ASDs are associated with the autosomal dominant **Holt-Oram syndrome**. The gene responsible for this syndrome, situated in the region 12q21-q22 of chromosome 12, is TBX5, a member of the T-box transcriptional family. A familial form of secundum ASD associated with AV conduction delay has been linked to mutations in the transcription factor Nkx2.5.

Treatment.

Surgery or transcatheter device closure is advised for all symptomatic patients and also for asymptomatic patients with a Qp:Qs ratio of at least 2:1. The timing for elective closure is usually after the 1st yr and before entry into school. Closure carried out at open heart surgery is associated with a mortality rate of less than 1%. Repair is preferred during early childhood because surgical mortality and morbidity are significantly greater in adulthood; the long-term risk of arrhythmia is also greater after ASD repair in adults. Atrial septal occlusion devices implanted transvenously at cardiac catheterization are approved for general use. In patients with small secundum ASDs and minimal left-to-right shunts, the consensus is that closure is not required. It is unclear at present whether the persistence of a small ASD into adulthood increases the risk for stroke enough to warrant prophylactic closure of all

these defects.

The results after surgical or device closure in children with large shunts are excellent. Symptoms disappear rapidly, and physical development frequently appears enhanced. Heart size decreases to normal, and the electrocardiogram shows decreased right ventricular forces. Late arrhythmias are less frequent in patients who have had early surgical repair. Although early and mid-term results are excellent, the long-term effects of device closure are not yet known.

419.3 Sinus Venosus Atrial Septal Defect

A sinus venosus ASD is situated in the upper part of the atrial septum in close relation to the entry of the superior vena cava. Often, one or more pulmonary veins (usually from the right lung) drain anomalously into the superior vena cava. Sometimes the superior vena cava straddles the defect; in this case, some systemic venous blood enters the left atrium, but only rarely does it cause clinically evident cyanosis. The hemodynamic disturbance, clinical picture, electrocardiogram, and roentgenogram are similar to those seen in secundum ASD. The diagnosis can usually be made by two-dimensional echocardiography. If cardiac catheterization is carried out to better define venous drainage, the catheter may enter a right pulmonary vein directly from the superior vena cava. Anatomic correction generally requires the insertion of a patch to close the defect while incorporating the entry of anomalous veins into the left atrium; surgical results are generally excellent. Rarely, sinus venosus defects involve the inferior vena cava.

419.4 Partial Anomalous Pulmonary Venous Return

One or several pulmonary veins may return anomalously to the superior or inferior vena cava, the right atrium, or the coronary sinus and produce a left-to-right shunt of oxygenated blood. Partial anomalous pulmonary venous return usually involves some or all of the veins from only one lung, more often the right one. When an associated ASD is present, it is generally of the sinus venosus type (see Chapter 419.3). When a sinus venosus ASD is detected by echocardiography, one must search for associated partial anomalous pulmonary venous return. The history, physical signs, and electrocardiographic and roentgenographic findings are indistinguishable from those of an isolated ostium secundum ASD. Occasionally, an anomalous vein draining into the inferior vena cava is visible on chest radiography as a crescentic shadow of vascular density along the right border of the cardiac silhouette (*scimitar syndrome*); in these cases, an ASD is not usually present, but pulmonary sequestration and anomalous arterial supply to that lobe are common findings. Total anomalous pulmonary venous return is a cyanotic lesion and is discussed in Chapter 424.7 . Echocardiography generally confirms the diagnosis. MRI and electron beam CT are also useful for defining pulmonary venous drainage. At cardiac catheterization, the presence of anomalous pulmonary veins may be demonstrated by selective pulmonary arteriography.

The prognosis is excellent, similar to that for ostium secundum ASDs. When a large left-to-right shunt is present, surgical repair is performed. The associated ASD should be closed in such a way that pulmonary venous return is directed to the left

atrium. A single anomalous pulmonary vein without an atrial communication may be difficult to redirect to the left atrium; if the shunt is small, it may be left unoperated.

419.5 Atrioventricular Septal Defects (Ostium Primum and Atrioventricular Canal or Endocardial Cushion Defects)

The abnormalities encompassed by AV septal defects are grouped together because they represent a spectrum of a basic embryologic abnormality, a deficiency of the AV septum. An *ostium primum defect* is situated in the lower portion of the atrial septum and overlies the mitral and tricuspid valves. In most instances, a cleft in the anterior leaflet of the mitral valve is also noted. The tricuspid valve is usually functionally normal, although some anatomic abnormality of the septal leaflet is generally present. The ventricular septum is intact.

An *AV septal defect*, also known as an AV canal defect or an endocardial cushion defect, consists of contiguous atrial and ventricular septal defects with markedly abnormal AV valves. The severity of the valve abnormalities varies considerably; in the complete form of AV septal defect, a single AV valve is common to both ventricles and consists of an anterior and a posterior bridging leaflet related to the ventricular septum, with a lateral leaflet in each ventricle. The lesion is common in children with Down syndrome and may occasionally occur with pulmonary stenosis.

Transitional varieties of these defects also occur and include ostium primum defects with clefts in the anterior mitral and septal tricuspid valve leaflets, minor ventricular septal deficiencies, and less commonly, ostium primum defects with normal AV valves. In some patients, the atrial septum is intact, but the inlet VSD simulates that found in the full AV septal defect. These defects are also commonly associated with deformities of the AV valves.

Pathophysiology.

The basic abnormality in patients with *ostium primum defects* is the combination of a left-to-right shunt across the atrial defect and mitral (or occasionally tricuspid) insufficiency. The shunt is usually moderate to large, the degree of mitral insufficiency is generally mild to moderate, and pulmonary arterial pressure is typically normal or only mildly increased. The physiology of this lesion is therefore similar to that of an ostium secundum ASD.

In *AV septal defects*, the left-to-right shunt occurs at both the atrial and ventricular levels (Fig. 419–2). Additional shunting may occur directly from the left ventricle to the right atrium because of absence of the AV septum. Pulmonary hypertension and an early tendency to increase pulmonary vascular resistance are common. AV valvular insufficiency increases the volume load on one or both ventricles. Some right-to-left shunting may also occur at both the atrial and ventricular levels and lead to mild but significant arterial desaturation. With time, progressive pulmonary vascular disease increases the right-to-left shunt so that clinical cyanosis develops

(Eisenmenger physiology, see Chapter 426.2).

Clinical Manifestations.

Many children with ostium primum *defects* are asymptomatic, and the anomaly is discovered during a general physical examination. In patients with moderate shunts and mild mitral insufficiency, the physical signs are similar to those of the secundum ASD, but with an additional apical murmur caused by mitral insufficiency.

A history of exercise intolerance, easy fatigability, and recurrent pneumonia may be obtained, especially in infants with large left-to-right

Figure 419.5-2 Physiology of atrioventricular septal defect (AVSD). Circled numbers represent oxygen saturation values. The numbers next to the arrows represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 3:1. Desaturated blood enters the right atrium from the vena cavae at a volume of 3?L/min/m^2 and mixes with 3?L of fully saturated blood shunting left to right across the atrial septal defect; the result is an increase in oxygen saturation in the right atrium. Six liters of blood flows through the right side of the common AV valve, joined by an additional 3?L of saturated blood shunting left to right at the ventricular level, further increasing oxygen saturation in the right ventricle. The full 9?L flows across the right ventricular outflow tract into the lungs. Nine liters returns to the left atrium, with 3?L shunting left to right across the defect and 6?L crossing the left side of the common AV valve and causing a mid-diastolic flow rumble. Three liters of this volume shunts left to right across the VSD, and 3?L is ejected into the ascending aorta (normal cardiac output).

shunts and severe mitral insufficiency. In these patients, cardiac enlargement is moderate or marked, and the precordium is hyperdynamic. Auscultatory signs produced by the left-to-right shunt include a normal or accentuated 1st sound; wide, fixed splitting of the 2nd sound; a pulmonary systolic ejection murmur sometimes preceded by a click; and a low-pitched, mid-diastolic rumbling murmur at the lower left sternal edge or apex, or both, as a result of increased flow through the AV valves. Mitral insufficiency may be manifested by an apical harsh (occasionally very high pitched) holosystolic murmur that radiates to the left axilla.

With *complete AV septal defects*, congestive heart failure and intercurrent pulmonary infection usually appear in infancy. During these episodes, minimal cyanosis may be evident. The liver is enlarged and the infant shows signs of failure to thrive. Cardiac enlargement is moderate to marked, and a systolic thrill is frequently palpable at the lower left sternal border. A precordial bulge and lift may be present as well. The 1st heart sound is normal or accentuated. The 2nd heart sound is widely split if the pulmonary flow is massive. A low-pitched, mid-diastolic rumbling murmur is audible at the lower left sternal border, and a pulmonary systolic ejection murmur is produced by the large pulmonary flow. The harsh apical holosystolic murmur of mitral insufficiency may also be present.

Diagnosis.

Chest *radiographs* of children with complete AV septal defects often show marked cardiac enlargement caused by the prominence of both ventricles and atria. The pulmonary artery is large, and pulmonary vascularity is increased.

The *electrocardiogram* in patients with a complete AV septal defect is distinctive. The principal abnormalities are (1) superior

---

orientation of the mean frontal QRS axis with left axis deviation to the left upper or right upper quadrant, (2) counterclockwise inscription of the superiorly oriented QRS vector loop, (3) signs of biventricular hypertrophy or isolated right ventricular hypertrophy, (4) right ventricular conduction delay (RSR' pattern in leads V_3 R and V_1), (5) normal or tall P waves, and (6) occasional prolongation of the P-R interval (Fig. 419–3).

The *echocardiogram* is characteristic and shows signs of right ventricular enlargement with encroachment of the mitral valve echo on the left ventricular outflow tract; the abnormally low position of the AV valves results in a “gooseneck” deformity of the left ventricular outflow tract on both echocardiography and angiography. In normal hearts, the tricuspid valve inserts slightly more toward the apex than the mitral valve does. In AV septal defects, both valves insert at the same level because of absence of the AV septum. In complete AV septal defects, the ventricular septal echo is also deficient and the common AV valve is readily appreciated (Fig. 419–4). Pulsed and color flow Doppler echocardiography will demonstrate left-to-right shunting at the atrial, ventricular, or ventricular-to-atrial levels and semiquantitate the degree of AV valve insufficiency. Echocardiography is useful for determining the insertion points of the chordae of the common AV valve and for evaluating the presence of associated lesions such as patent ductus arteriosus (PDA) or coarctation of the aorta.

Cardiac catheterization and *angiocardiography* may be required to confirm the diagnosis, although most patients can be operated on without catheterization. These studies demonstrate the magnitude of the left-to-right shunt, the severity of pulmonary hypertension, the degree of elevation of pulmonary vascular resistance, and the severity of insufficiency of the common AV valve. By oximetry, the shunt is usually demonstrable at both the atrial and ventricular levels. Arterial oxygen saturation is normal or only mildly reduced unless severe pulmonary vascular disease is present. Children with ostium primum defects generally have normal or only moderately elevated pulmonary arterial pressure. Conversely, complete AV septal defects are associated with right ventricular and pulmonary hypertension and, in older patients, with increased pulmonary vascular resistance (see Chapter 426.2).

Selective left ventriculography is extremely helpful in the diagnosis of AV septal defects. The deformity of the mitral or common AV valve and the distortion of the outflow tract of the left ventricle cause a “gooseneck”-appearing deformity of the left ventricular outflow tract. The abnormal anterior leaflet of the mitral valve is serrated, and mitral insufficiency is noted, usually with regurgitation of blood into both the left and right atria. Direct shunting of blood from the left ventricle to the right atrium may also be demonstrated.

Figure 419.5-3 Electrocardiogram from a child with an atrioventricular canal. Note the QRS axis of

-60 degrees and the right ventricular conduction delay with an RSR' pattern in V1 and V3R (V3R paper speed = 50?mm/sec).

Prognosis and Complications.

The prognosis for complete AV septal defects depends on the magnitude of the left-to-right shunt, the degree of elevation of pulmonary vascular resistance, and the severity of AV valve insufficiency. Death from cardiac failure during infancy used to be frequent before the advent of early corrective surgery. In patients who survived without surgery, pulmonary vascular obstructive disease or, more rarely, pulmonic stenosis usually developed. Most patients with ostium primum defects and minimal AV valve involvement are asymptomatic or have only minor, nonprogressive symptoms until they reach the 3rd–4th decade of life, similar to the course of patients with secundum ASDs.

Treatment.

Ostium primum defects are approached surgically from an incision in the right atrium. The cleft in the mitral valve is located through the atrial defect and is repaired by direct suture. The defect in the atrial septum is usually closed by insertion of a patch prosthesis. The surgical mortality rate for ostium primum defects is low. Surgical treatment of complete AV septal defects is more difficult, especially in infants with cardiac failure and pulmonary hypertension. Because of the risk of pulmonary vascular disease developing as early as 6–12 mo of age, surgical intervention must be performed during infancy. Correction of these defects can be accomplished in infancy, and palliation with pulmonary arterial banding is reserved for the subset of patients

Figure 419.5-4 Echocardiogram of an atrioventricular septal defect. *A*, Four-chamber view demonstrating both an interatrial and an interventricular septal defect contributing to the large central communication of this lesion (arrows). *B*, Left ventricular long-axis projection demonstrating the typical gooseneck deformity created by the anterior leaflet of the mitral valve (arrows). RA = right atrium; LA = left atrium; RVI = right ventricular inflow; LV = left ventricle; R = right; L = left; S = superior; I = inferior; Ao = aorta.

who are either too small or have other associated lesions that make early corrective surgery too risky. The atrial and ventricular defects are patched and the AV valves reconstructed. Complications include surgically induced heart block requiring placement of a permanent pacemaker, excessive narrowing of the left ventricular outflow tract requiring surgical revision, and eventual worsening of mitral regurgitation requiring replacement with a prosthetic valve.

419.6 Ventricular Septal Defect

VSD is the most common cardiac malformation and accounts for 25% of congenital heart disease. Defects may occur in any portion of the ventricular septum, but most are of the membranous type. These defects are in a posteroinferior position, anterior to the septal leaflet of the tricuspid valve. VSDs between the crista supraventricularis and the papillary muscle of the conus may be associated with pulmonary stenosis and other manifestations of the tetralogy of Fallot (see Chapter 423.1). VSDs superior to the crista supraventricularis (supracristal) are less common; they are found just beneath the pulmonary valve and may impinge on an aortic sinus and cause aortic insufficiency. VSDs in the midportion or apical region of the ventricular septum are muscular in type and may be single or multiple (Swiss cheese septum).

Pathophysiology.

The physical size of the VSD is a major, but not the only determinant of the size of the left-to-right shunt. The level of pulmonary vascular resistance in relation to systemic vascular resistance also determines the shunt's magnitude. When a small communication is present (usually <0.5?cm^2), the VSD is called *restrictive* and right ventricular pressure is normal. The higher pressure in the left ventricle drives the shunt left to right; the size of the defect limits the magnitude of the shunt. In large *nonrestrictive* VSDs (usually >1.0?cm^2), right and left ventricular pressure is equalized. In these defects, the direction of shunting and shunt magnitude are determined by the ratio of pulmonary to systemic vascular resistance (Fig. 419–5).

After birth in patients with a large VSD, pulmonary vascular resistance may remain higher than normal, and thus the size of the left-to-right shunt may initially be limited. As pulmonary vascular resistance continues to fall in the 1st few weeks after birth because of normal involution of the media of small pulmonary arterioles, the size of the left-to-right shunt increases. Eventually, a large left-to-right shunt develops, and clinical symptoms become apparent. In most cases during early infancy, pulmonary vascular resistance is only slightly elevated, and the major contribution to pulmonary hypertension is the extremely large pulmonary blood flow. However, in some infants with a large VSD, pulmonary arteriolar medial thickness never decreases. With continued exposure of the pulmonary vascular bed to high systolic pressure and high flow, pulmonary vascular obstructive disease develops. When the ratio of pulmonary to systemic resistance approaches 1:1, the shunt becomes bidirectional, the signs of heart failure abate, and the patient becomes cyanotic (Eisenmenger physiology, see Chapter 426.2).

The magnitude of intracardiac shunts is usually described by the Qp:Qs ratio. If the left-to-right shunt is small (Qp:Qs <1.75:1), the cardiac chambers are not appreciably enlarged and the pulmonary vascular bed is probably normal. If the shunt is large (Qp:Qs >2:1), left atrial and ventricular volume overload occurs, as does right ventricular and pulmonary arterial hypertension. The main pulmonary artery, left atrium, and left ventricle are enlarged.

Clinical Manifestations.

The clinical findings of patients with a VSD vary according to the size of the defect and pulmonary blood flow and pressure. *Small VSDs* with trivial left-to-right shunts and normal pulmonary arterial pressure are the most

Figure 419.6-5 Physiology of a large ventricular septal defect (VSD). Circled numbers represent oxygen saturation values. The numbers next to the arrows represent volumes of blood flow (in

L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 2:1. Desaturated blood enters the right atrium from the vena cava at a volume of 3?L/min/m^2 and flows across the tricuspid valve. An additional 3?L of blood shunts left to right across the VSD, the result being an increase in oxygen saturation in the right ventricle. Six liters of blood is ejected into the lungs. Pulmonary arterial saturation may be further increased because of incomplete mixing at right ventricular level. Six liters returns to the left atrium, crosses the mitral valve, and causes a mid-diastolic flow rumble. Three liters of this volume shunts left to right across the VSD, and 3?L is ejected into the ascending aorta (normal cardiac output).

common. These patients are asymptomatic, and the cardiac lesion is usually found during routine physical examination. Characteristically, a loud, harsh, or blowing holosystolic murmur is present and heard best over the lower left sternal border, and it is frequently accompanied by a thrill. In a few instances the murmur ends before the 2nd sound, presumably because of closure of the defect during late systole. A short, harsh systolic murmur localized to the apex in a neonate is often a sign of a tiny muscular VSD. In the immediate neonatal period, the left-to-right shunt may be minimal because of higher right-sided pressure, and therefore the systolic murmur may not be audible during the 1st few days of life. In premature infants, the murmur may be heard early because pulmonary vascular resistance decreases more rapidly.

Large VSDs with excessive pulmonary blood flow and pulmonary hypertension are responsible for dyspnea, feeding difficulties, poor growth, profuse perspiration, recurrent pulmonary infections, and cardiac failure in early infancy. Cyanosis is usually absent, but duskiness is sometimes noted during infections or crying. Prominence of the left precordium is common, as are a palpable parasternal lift, a laterally displaced apical impulse and apical thrust, and a systolic thrill. The holosystolic murmur of a large VSD is generally less harsh than that of a small VSD and more blowing in nature because of the absence of a significant pressure gradient across the defect. It is even less likely to be audible in the newborn period. The pulmonic component of the 2nd heart sound may be increased as a result of pulmonary hypertension. The presence of a mid-diastolic, low-pitched rumble at the apex is caused by increased blood flow across the mitral valve and indicates a Qp:Qs ratio of 2:1

or greater. This murmur is best appreciated with the bell of the stethoscope.

Diagnosis.

In patients with small VSDs, the *chest radiograph* is usually normal, although minimal cardiomegaly and a borderline increase in pulmonary vasculature may be observed. The *electrocardiogram* is generally normal but may suggest left ventricular hypertrophy. The presence of right ventricular hypertrophy is a warning that the defect is not small and that the patient has pulmonary hypertension or an associated lesion such as pulmonic stenosis. In large VSDs, the *chest radiograph* shows gross cardiomegaly with prominence of both ventricles, the left atrium, and the pulmonary artery. Pulmonary vascular markings are increased, and frank pulmonary edema, including pleural effusions, may be present. The *electrocardiogram* shows biventricular hypertrophy; P waves may be notched or peaked.

The *two-dimensional echocardiogram* shows the position and size of the VSD. In small defects, especially those of the muscular septum, the defect itself may be difficult to image and is visualized only by color Doppler examination. In defects of the membranous septum, a thin membrane (called a *ventricular septal aneurysm* but consisting of tricuspid valve tissue) can partially cover the defect and limit the volume of the left-to-right shunt. Echocardiography is also useful for estimating shunt size by examining the degree of volume overload of the left atrium and left ventricle; in the absence of associated lesions, the extent of their increased dimensions is a good reflection of the size of the left-to-right shunt. Pulsed Doppler examination shows whether the VSD is pressure restrictive by calculating the pressure gradient across the defect. Such calculation allows an estimation of right ventricular pressure and helps determine whether the patient is at risk for the development of early pulmonary vascular disease. In addition, the echocardiogram can be useful to determine the presence of aortic valve insufficiency or leaflet prolapse in the case of supracristal VSDs.

The hemodynamics of a VSD can also be demonstrated by *cardiac catheterization*. Catheterization is usually performed only when the size of the shunt is uncertain after a comprehensive clinical evaluation, when laboratory data do not fit well with the clinical findings, or when pulmonary vascular disease is suspected. Oximetry demonstrates increased oxygen content in the right ventricle; because some defects eject blood almost directly into the pulmonary artery (streaming), this increase is occasionally apparent only when pulmonary arterial blood is sampled. Small, restrictive VSDs are associated with normal right-sided heart pressure and pulmonary vascular resistance. Large, nonrestrictive VSDs are associated with equal or nearly equal pulmonary and systemic systolic pressure. Pulmonary blood flow may be two to four times systemic blood flow. In patients with such “hyperdynamic pulmonary hypertension,” pulmonary vascular resistance is only minimally elevated because resistance is equal to pressure divided by flow. If Eisenmenger syndrome is present, pulmonary artery systolic and diastolic pressure is elevated, the degree of left-to-right shunting is minimal, and desaturation of blood in the left ventricle is encountered. The size, location, and number of ventricular defects are demonstrated by left ventriculography. Contrast medium passes across the defect or defects to opacify the right ventricle and pulmonary artery.

Prognosis and Complications.

The natural course of a VSD depends to a large degree on the size of the defect. A significant number (30–50%) of small defects close spontaneously, most frequently during the 1st 2 yr of life. Small muscular VSDs are more likely to close (up to 80%) than membranous VSDs are (up to 35%). The vast majority of defects that close do so before the age of 4 yr, although spontaneous closure has been reported in adults. These VSDs often have ventricular septal aneurysms limiting the magnitude of the shunt. Most children with small defects remain asymptomatic, without evidence of an increase in heart size, pulmonary arterial pressure, or resistance. A long-term risk is infective endocarditis. Some long-term studies of adults with unoperated small VSDs show an increased incidence of arrhythmia, subaortic stenosis, and exercise intolerance. The Council on Cardiovascular Disease in the Young of the American Heart Association states that an isolated, small, hemodynamically insignificant VSD is not an indication for surgery. The declining risk of open heart surgery has led

others to suggest that all VSDs be closed electively by mid-childhood.

It is less common for moderate or large VSDs to close spontaneously, although even defects large enough to result in heart failure may become smaller and up to 8% may close completely. More commonly, infants with large defects have repeated episodes of respiratory infection and heart failure despite optimal medical management. Heart failure may be manifested in many of these infants primarily as failure to thrive. Pulmonary hypertension occurs as a result of high pulmonary blood flow. These patients are at risk for pulmonary vascular disease with time if the defect is not repaired.

Patients with VSD are also at risk for the development of aortic valve regurgitation, the greatest risk occurring in patients with supracristal VSD (see Chapter 419.7). A small number of patients with VSD have acquired infundibular pulmonary stenosis, which then protects the pulmonary circulation from the short-term effects of pulmonary overcirculation and the long-term effects of pulmonary vascular disease. In these patients, the clinical picture changes from that of a VSD with a large left-to-right shunt to a VSD with pulmonary stenosis. The shunt may diminish in size, become balanced, or even become a net right-to-left shunt (see Chapter 423). These patients must be distinguished from those in whom an Eisenmenger physiology develops (see Chapter 426.2).

Treatment.

In patients with small VSDs, parents should be reassured of the relatively benign nature of the lesion, and the child should be encouraged to live a normal life, with no restrictions on physical activity. Surgical repair is currently not recommended. As protection against infective endocarditis, the integrity of primary and permanent teeth should be carefully maintained; antibiotic prophylaxis should be provided for dental visits (including cleanings), tonsillectomy, adenoidectomy, and other oropharyngeal surgical procedures, as well as for instrumentation of the genitourinary and lower intestinal tracts (see Chapter 429). These patients can be monitored by a combination of clinical examination and noninvasive laboratory tests until the VSD has closed spontaneously. The electrocardiogram is an excellent means of screening these patients for possible pulmonary hypertension or pulmonic stenosis as indicated by right ventricular hypertrophy. Echocardiography is used to screen for the development of left ventricular outflow tract pathology (subaortic membrane or aortic regurgitation) and to confirm spontaneous closure.

In infants with a large VSD, medical management has two aims: to control heart failure and prevent the development of pulmonary vascular disease. Therapeutic measures are aimed at control of the heart failure symptoms and maintenance of normal growth (see Chapter 434). If early treatment is successful, the shunt may diminish in size with spontaneous improvement, especially during the 1st yr of life. The clinician must be alert to not confuse clinical improvement caused by a decrease in defect size with clinical changes caused by the development of Eisenmenger physiology. Because surgical closure can be carried out at low risk in most infants, medical management should not be pursued in symptomatic infants after an initial unsuccessful trial. Pulmonary vascular disease can be prevented when surgery is performed within the 1st yr of life.

Indications for surgical closure of a VSD include patients at any age with large defects in whom clinical symptoms and failure to thrive cannot be controlled medically; infants between 6

---

and 12 mo of age with large defects associated with pulmonary hypertension, even if the symptoms are controlled by medication; and patients older than 24 mo with a Qp:Qs ratio greater than 2:1. Patients with supracristal VSD of any size are usually referred for surgery because of the high risk for aortic valve regurgitation (see Chapter 419.7). Severe pulmonary vascular disease is a contraindication to closure of a VSD.

The results of primary surgical repair are excellent, and complications leading to long-term problems (e.g., residual ventricular shunts requiring reoperation or heart block requiring a pacemaker) are rare. Pulmonary arterial palliative banding with repair in later childhood is reserved for complicated cases or very premature infants. Surgical risks are higher for defects in the muscular septum, particularly apical defects and multiple (Swiss cheese type) VSDs. These patients may require pulmonary arterial banding if symptomatic, with subsequent debanding and repair of multiple VSDs at an older age. Clamshell-type catheter occlusion devices are being tested as a means of closing apical muscular VSDs.

After obliteration of the left-to-right shunt, the hyperdynamic heart becomes quiet, cardiac size decreases toward normal (Fig. 419–6), thrills and murmurs are abolished, and pulmonary artery hypertension regresses. The patient's clinical status improves markedly. Most infants begin to thrive, and cardiac medications are no longer required. Catch-up growth occurs in most patients over the next 1–2 yr. In some instances after successful surgery, systolic ejection murmurs of low intensity may persist for months. The long-term prognosis after surgery is excellent. Patients with a small VSD and those who have undergone surgical closure without residua are considered to be at standard risk for health insurance.

419.7 Supracristal Ventricular Septal Defect with Aortic Insufficiency

A supracristal VSD is complicated by prolapse of the aortic valve into the defect and aortic insufficiency, which may eventually occur in 50–90% of patients. Although it accounts for approximately 5% of all patients with VSD, the incidence is highest in Asian children. The VSD, which may be small or moderate in size, is located anterior to and directly below the pulmonary valve in the outlet septum, superior to the crista supraventricularis. In occasional cases, aortic insufficiency is associated with VSDs located in the membranous septum. The right or, less often, the noncoronary aortic cusp prolapses into the defect and may partially or even completely occlude it. Such occlusion may limit the amount of left-to-right shunting and give the false impression that the defect is not large. Aortic insufficiency is most often not recognized until late in the 1st decade of life or beyond.

Early heart failure secondary to a large left-to-right shunt rarely occurs, but without surgery, severe aortic insufficiency and left ventricular failure may ensue. The murmur of a supracristal VSD is usually heard at the middle to upper left sternal

border, as opposed to the lower left sternal border, and it is sometimes confused with that of pulmonic stenosis. The physical signs of aortic insufficiency (diastolic murmur and wide pulse pressure), when present, are added to those of the VSD. These clinical findings must be distinguished from PDA or other defects associated with aortic runoff.

The *clinical manifestations* vary widely from trivial aortic regurgitation and small left-to-right shunts in asymptomatic children to florid aortic incompetence and massive cardiomegaly in symptomatic adolescents. Closure of all supracristal ventricular VSDs at the time of diagnosis is commonly recommended to prevent the development of aortic regurgitation, even in an asymptomatic child. Patients who already have significant aortic incompetence require surgical intervention to prevent irreversible left ventricular dysfunction. Surgical options depend on the degree of damage to the valve and include valvuloplasty for mild involvement and replacement with a prosthesis or homograft or aortopulmonary translocation (see Chapter 420.5) for severe involvement.

419.8 Patent Ductus Arteriosus

During fetal life, most of the pulmonary arterial blood is shunted through the ductus arteriosus into the aorta (see

Figure 419.8-6 *A*, Preoperative roentgenogram in a patient with a ventricular septal defect with a large left-to-right shunt and pulmonary hypertension. Significant cardiomegaly, prominence of the pulmonary arterial trunk, and pulmonary overcirculation are evident. *B*, Three years after surgical closure of the defect, heart size is markedly decreased, and the pulmonary vasculature is normal.

Chapter 414). Functional closure of the ductus normally occurs soon after birth, but if the ductus remains patent when pulmonary vascular resistance falls, aortic blood is shunted into the pulmonary artery. The aortic end of the ductus is just distal to the origin of the left subclavian artery, and the ductus enters the pulmonary artery at its bifurcation. Female patients with PDA outnumber males 2:1. PDA is also associated with maternal rubella infection during early pregnancy. It is a common problem in premature infants, where it can cause severe hemodynamic derangements and several major sequelae (see Chapter 90.3).

When a term infant is found to have a PDA, the wall of the ductus is deficient in both the mucoid endothelial layer and the muscular media. In a premature infant, the PDA usually has a normal structure; patency is the result of hypoxia and immaturity. Thus, a PDA persisting beyond the 1st few weeks of life in a term infant rarely closes spontaneously or with pharmacologic intervention, whereas if early pharmacologic or surgical intervention is not required in a premature infant, spontaneous closure occurs in most instances. A PDA is seen in 10% of patients with other congenital heart lesions and often plays a critical role in providing pulmonary blood flow when the right ventricular outflow tract is stenotic or atretic (see Chapter 423) or in providing systemic blood flow in the presence of aortic coarctation or interruption (see Chapter 420).

Pathophysiology.

As a result of the higher aortic pressure, blood shunts left to right through the ductus, from the aorta to the pulmonary artery. The extent of the shunt depends on the size of the ductus and on the ratio of pulmonary to systemic vascular resistance. In extreme cases, 70% of the left ventricular output may be shunted through the ductus to the pulmonary circulation. If the PDA is small, pressure within the pulmonary artery, the right ventricle, and the right atrium is normal. However, if the PDA is large, pulmonary artery pressure may be elevated to systemic levels during both systole and diastole. Patients with a large PDA are at extremely high risk for the development of pulmonary vascular disease if left unoperated. Pulse pressure is wide because of runoff of blood into the pulmonary artery during diastole.

Clinical Manifestations.

A small patent ductus does not usually have any symptoms associated with it. A large PDA will result in heart failure similar to that encountered in infants with a large VSD. Retardation of physical growth may be a major manifestation in infants with large shunts.

A large PDA will result in striking physical signs attributable to the wide pulse pressure, most prominently, bounding peripheral arterial pulses. The heart is normal in size when the ductus is small but moderately or grossly enlarged in cases with a large communication. The apical impulse is prominent and, with cardiac enlargement, is heaving. A thrill, maximal in the 2nd left interspace, is often present and may radiate toward the left clavicle, down the left sternal border, or toward the apex. It is usually systolic but may also be palpated throughout the cardiac cycle. The classic continuous murmur is described as being like machinery or rolling thunder in quality. It begins soon after onset of the 1st sound, reaches maximal intensity at the end of systole, and wanes in late diastole. It may be localized to the 2nd left intercostal space or radiate down the left sternal border or to the left clavicle. When pulmonary vascular resistance is increased, the diastolic component of the murmur may be less prominent or absent. In patients with a large left-to-right shunt, a low-pitched mitral mid-diastolic murmur may be audible at the apex as a result of the increased volume of blood flow across the mitral valve.

Diagnosis.

If the left-to-right shunt is small, the *electrocardiogram* is normal; if the ductus is large, left ventricular or biventricular hypertrophy is present. The diagnosis of an isolated, uncomplicated PDA is untenable when right ventricular hypertrophy is noted.

Radiographic studies in patients with a large PDA show a prominent pulmonary artery with increased intrapulmonary vascular markings. Cardiac size depends on the degree of left-to-right shunting; it may be normal or moderately to markedly enlarged. The chambers involved are the left atrium and ventricle. The aortic knob is normal or prominent.

The *echocardiographic* view of the cardiac chambers is normal if the ductus is small. With large shunts, left atrial and left ventricular dimensions are increased. The size of the left atrium is usually quantitated by comparison to the size of the aortic root, known as the LA:Ao ratio. Scanning from the suprasternal notch allows direct visualization of the ductus. Color and pulsed Doppler examinations demonstrate systolic or diastolic (or both) retrograde turbulent flow in the pulmonary artery and aortic retrograde flow in diastole.

The clinical pattern is sufficiently distinctive to allow an accurate diagnosis by noninvasive methods in most patients. In patients with atypical findings or when associated cardiac lesions are suspected, cardiac catheterization may be indicated. *Cardiac catheterization* demonstrates normal or increased pressure in the right ventricle and pulmonary artery, depending on the size of the ductus. The presence of oxygenated blood shunting into the pulmonary artery confirms a left-to-right shunt. The catheter may pass from the pulmonary artery through the ductus into the descending aorta. Injection of contrast medium into the ascending aorta shows opacification of the pulmonary artery from the aorta and identifies the ductus.

Other conditions can produce systolic and diastolic murmurs in the pulmonic area in the absence of cyanosis and must be differentiated. The characteristics of a venous hum are described in Chapter 415 . An aorticopulmonary window defect may rarely be clinically indistinguishable from a patent ductus, although in most cases the murmur is only systolic and is loudest at the right rather than the left upper sternal border. A sinus of Valsalva aneurysm that has ruptured into the right side of the heart or pulmonary artery, coronary arteriovenous fistulas, and an aberrant left coronary artery with massive collaterals from the right coronary display dynamics similar to that of a PDA with a continuous murmur and a wide pulse pressure. Truncus arteriosus with torrential pulmonary flow also has an “aortic runoff” physiology. Pulmonary branch stenosis can be associated with systolic and diastolic murmurs, but the pulse pressure will be normal. A peripheral arteriovenous fistula also results in a wide pulse pressure, but the distinctive murmur of a PDA is not present. VSD with aortic insufficiency and combined rheumatic aortic and mitral insufficiency may be confused with a PDA, but the murmurs should be differentiated by their to-and-fro rather than continuous nature. The combination of a large VSD and a PDA results in findings more like those of an isolated VSD. Echocardiography should be able to eliminate these other diagnostic possibilities. If a PDA is suspected clinically but not visualized on echocardiography, cardiac catheterization is usually indicated.

Prognosis and Complications.

Patients with a small PDA may live a normal span with few or no cardiac symptoms, but late manifestations may occur. Spontaneous closure of the ductus after infancy is extremely rare. *Cardiac failure* most often occurs in early infancy in the presence of a large ductus but may occur late in life even with a moderate-sized communication. The chronic left ventricular volume load is less well tolerated with aging.

Infective endarteritis may be seen at any age. Pulmonary or systemic emboli may occur. Rare complications include aneurysmal dilatation of the pulmonary artery or the ductus, calcification of the ductus, noninfective thrombosis of the ductus with embolization, and paradoxical emboli. Pulmonary hypertension (Eisenmenger syndrome) usually develops in

patients with a large PDA who do not undergo surgical treatment (see Chapter 426.2).

Treatment.

Irrespective of age, patients with PDA require surgical or catheter closure. In patients with a small PDA, the rationale for closure is prevention of bacterial endarteritis or other late complications. In patients with a moderate to large PDA, closure is accomplished to treat heart failure or prevent the development of pulmonary vascular disease, or both. Once the diagnosis of a moderate to large PDA is made, treatment should not be unduly postponed after adequate medical therapy for cardiac failure has been instituted.

Surgical closure of PDA can be accomplished by thoracoscopic techniques to minimize scarring and reduce postoperative discomfort. Because the case fatality rate with surgical treatment is considerably less than 1% and the risk without it is greater, ligation and division of the ductus are indicated in asymptomatic patients, preferably before 1 yr of age. Pulmonary hypertension is not a contraindication to surgery at any age if it can be demonstrated at cardiac catheterization that the shunt flow is still predominantly left to right and that severe pulmonary vascular disease is not present. After closure, symptoms of frank or incipient cardiac failure rapidly disappear. Infants who had failed to thrive usually have immediate improvement in physical development. The pulse and blood pressure return to normal, and the machinery-like murmur disappears. A functional systolic murmur over the pulmonary area may persist; it may represent turbulence in a persistently dilated pulmonary artery. The radiographic signs of cardiac enlargement and pulmonary overcirculation disappear over a period of several months, and the electrocardiogram becomes normal.

Transcatheter PDA closure is routinely performed in the cardiac catheterization laboratory. Small PDAs are generally closed with intravascular coils. Moderate to large PDAs may be closed with a catheter-introduced sac into which several coils are released or with an umbrella-like device.

Patent Ductus Arteriosus in Low-Birthweight Infants.

See Chapter 90.3 .

419.9 Aorticopulmonary Window Defect

An aorticopulmonary window defect consists of a communication between the ascending aorta and the main pulmonary artery. The presence of pulmonary and aortic valves and an intact ventricular septum distinguishes this anomaly from truncus arteriosus (see Chapter 424.8). Symptoms of heart failure appear during early infancy; occasionally, minimal cyanosis is present. The defect is usually large,

and the cardiac murmur is systolic with a mid-diastolic rumble as a result of the increased blood flow across the mitral valve. In the rare instance when the communication is somewhat smaller and pulmonary hypertension is absent, the findings on examination can mimic those of a PDA (wide pulse pressure and a continuous murmur at the upper sternal borders). The electrocardiogram shows either left ventricular or biventricular hypertrophy. Radiographic studies demonstrate cardiac enlargement and prominence of the pulmonary artery and intrapulmonary vasculature. The echocardiogram shows enlarged left-sided heart chambers; the window defect can best be delineated with color flow Doppler.

Cardiac catheterization reveals a left-to-right shunt at the level of the pulmonary artery, as well as hyperkinetic pulmonary hypertension, because the defect is almost always large. Selective aortography with injection of contrast medium into the ascending aorta demonstrates the lesion, and manipulation of the catheter from the main pulmonary artery directly to the ascending aorta is also diagnostic.

An aorticopulmonary window defect is surgically corrected during infancy with cardiopulmonary bypass. If surgery is not carried out in infancy, survivors carry the risk of progressive pulmonary vascular obstructive disease, similar to that of other patients who have large intracardiac or great vessel communications.

419.10 Coronary-Arteriovenous Fistula (Coronary-Cameral Fistula)

A congenital fistula may exist between a coronary artery and an atrium, ventricle (especially the right), or pulmonary artery. Sometimes, multiple fistulas exist. Regardless of the recipient chamber, the clinical signs are similar to those of PDA, although the machinery-like murmur may be more diffuse. If the flow is substantial, the involved coronary artery may be dilated or aneurysmal. The anatomic abnormality is usually demonstrable by color flow Doppler echocardiography and, during catheterization, by injection of contrast medium into the ascending aorta. Small fistulas may be hemodynamically insignificant and may even close spontaneously. If the shunt is large, treatment consists of either transcatheter coil embolization or, for lesions not amenable to catheter intervention, surgical closure of the fistula.

419.11 Ruptured Sinus of Valsalva Aneurysm

When one of the sinuses of Valsalva of the aorta is weakened by congenital or acquired disease, an aneurysm may form and eventually rupture, usually into the right atrium or ventricle. This condition is extremely rare in childhood. The onset is usually sudden. The diagnosis should be suspected in a patient in whom symptoms of acute heart failure develop in association with a new loud to-and-fro murmur. Color Doppler echocardiography and cardiac catheterization demonstrate the left-to-right shunt at the atrial or ventricular level. Urgent surgical repair is generally required. This condition is often associated with infective endocarditis of the aortic valve.

Chapter 420 - Acyanotic Congenital Heart Disease: The Obstructive Lesions

420.1 Pulmonary Valve Stenosis with Intact Ventricular Septum

Of the various forms of right ventricular outflow obstruction with an intact ventricular septum, the most common is isolated valvular pulmonary stenosis, which accounts for 7–10% of all congenital heart defects. In this entity, the valve cusps are deformed to various degrees, and as a result the valve opens incompletely during systole. The valve may be bicuspid or tricuspid and the leaflets partially fused together with an eccentric outlet. This fusion may be so severe that only a pinhole central opening remains. If the valve is not severely thickened, it produces a domelike obstruction to right ventricular outflow during systole. Isolated infundibular stenosis, supravalvular pulmonary stenosis, and branch pulmonary artery stenosis are less commonly encountered. When pulmonary valve stenosis is the dominant lesion, a small associated ventricular septal defect (VSD) is present, and this condition is better classified as pulmonary stenosis with VSD than as tetralogy of Fallot. Pulmonary stenosis and an atrial septal defect (ASD) are occasionally seen as associated defects. The clinical and laboratory findings reflect the dominant lesion, but it is important to rule out these associated anomalies. Pulmonary stenosis as a result of valve dysplasia is the common cardiac abnormality of *Noonan syndrome* (see Chapter 70), and it is associated with a mutation in the region 12q24.1 on chromosome 12. The mechanism for pulmonic stenosis is unknown, although maldevelopment of the distal portion of the bulbus cordis and the sequelae of fetal endocarditis have been suggested as causes. Pulmonary stenosis, either of the valve or the branch pulmonary arteries, is a common finding in patients with arteriohepatic dysplasia, also known as **Alagille syndrome**. In this syndrome and in some patients with isolated pulmonic stenosis, a mutation is present in the *Jagged1* gene.

Pathophysiology.

The obstruction to outflow from the right ventricle to the pulmonary artery results in increased systolic pressure and wall stress, which eventually leads to hypertrophy of the right ventricle (Fig. 420–1). The severity of these abnormalities depends on the size of the restricted valve opening. In severe cases, right ventricular pressure may be higher than systemic arterial systolic pressure, whereas with milder obstruction, right ventricular pressure is only mildly or moderately elevated. Pulmonary artery pressure is normal or decreased. Arterial oxygen saturation will be normal even in cases of severe stenosis, unless an intracardiac communication such as a VSD or ASD is allowing blood to shunt from right to left. When severe pulmonic stenosis

occurs in a neonate, markedly decreased right ventricular compliance may lead to right-to-left shunting through a patent foramen ovale, a condition termed **critical pulmonic stenosis**.

Clinical Manifestations.

Patients with mild or moderate stenosis usually do not have any symptoms. Growth and development are most often normal; older infants and children appear to be well developed and healthy. If the stenosis is severe, signs of right ventricular failure such as hepatomegaly, peripheral edema, and exercise intolerance may be present. In a neonate or young infant with critical pulmonic stenosis, signs of right ventricular failure may be more prominent, and cyanosis is often present because of shunting at the foramen ovale.

Figure 420.1-1 Physiology of valvular pulmonary stenosis. *Boxed numbers* represent pressure in mm?Hg. Because of the absence of right-to-left or left-to-right shunting, blood flow through all cardiac chambers is normal at 3 L/min/m^2 . The pulmonary-to-systemic blood flow ratio (Qp:Qs) is 1:1. Right atrial pressure is increased slightly as a result of decreased right ventricular compliance. The right ventricle is hypertrophied, and systolic and diastolic pressure is increased. The pressure gradient across the thickened pulmonary valve is 60?mm Hg. The main pulmonary artery pressure is slightly low, and poststenotic dilatation is present. Left heart pressure is normal. Unless right-to-left shunting is occurring through a foramen ovale, the patient's systemic oxygen saturation will be normal.

With **mild pulmonary stenosis**, venous pressure and pulse are normal. The heart is not enlarged, the apical impulse is normal, and the right ventricular impulse is not palpable. A sharp pulmonic ejection click immediately following the 1st heart sound is heard at the left upper sternal border during expiration. The 2nd heart sound is split, with a pulmonary component of normal intensity that may be slightly delayed. A relatively short, low- or medium-pitched systolic ejection murmur is maximally audible over the pulmonic area and radiates minimally to the lung fields bilaterally. The *electrocardiogram* is normal or characteristic of mild right ventricular hypertrophy; inversion of the T waves in the right precordial leads may be seen. The only abnormality demonstrable *radiographically* is poststenotic dilatation of the pulmonary artery. *Two-dimensional echocardiography* shows right ventricular hypertrophy and a slightly thickened and domed pulmonic valve; Doppler studies demonstrate a right ventricle–to–pulmonary artery gradient of 30?mm Hg or less.

In **moderate pulmonic stenosis,** venous pressure may be slightly elevated; in older children, a prominent *a* wave may be noted in the jugular pulse. A right ventricular lift may be palpable at the lower left sternal border. The 2nd heart sound is split, with a delayed and diminished pulmonary component. As valve motion becomes more limited with more severe degrees of stenosis, both the pulmonic ejection click and the pulmonic 2nd sound may become inaudible. With increasing degrees of stenosis, the peak of the systolic ejection murmur is prolonged later into systole, and its quality becomes louder and harsher (higher frequency). The murmur radiates more prominently to both lung fields.

The *electrocardiogram* reveals varying degrees of right ventricular hypertrophy, sometimes with a prominent spiked P wave. *Radiographically*, the heart can vary from normal size to mildly enlarged because of prominence of the right ventricle; intrapulmonary vascularity may be normal or slightly decreased. The *echocardiogram* shows a thickened pulmonic valve with restricted systolic motion. Doppler examination demonstrates a ventricular–pulmonary artery pressure gradient in the 30–60?mm Hg range. Mild tricuspid regurgitation may be present and allows Doppler confirmation of right ventricular systolic pressure.

In **severe stenosis,** mild to moderate cyanosis may be noted in those with interatrial communication. If hepatic enlargement and peripheral edema are present, they are an indication of right ventricular failure. Elevation of venous pressure is common and is caused by a large presystolic jugular “*a*” wave. The heart is moderately or greatly enlarged, and a conspicuous parasternal right ventricular lift is present and frequently extends to the midclavicular line. The pulmonary element of the 2nd sound is usually inaudible. A loud and long harsh systolic ejection murmur, frequently accompanied by a thrill, is maximally audible in the pulmonic area and may radiate widely over the entire precordium, to both lung fields, into the neck, and to the back. The peak of the murmur occurs later in systole as valve opening becomes more restricted. The murmur frequently encompasses the aortic component of the 2nd sound but is not preceded by an ejection click.

The *electrocardiogram* shows gross right ventricular hypertrophy, frequently accompanied by a tall, spiked P wave. *Radiographic studies* confirm the cardiac enlargement and prominence of the right ventricle and atrium. Prominence of the pulmonary artery segment is due to poststenotic dilatation (Fig. 420–2). Intrapulmonary vascularity is decreased. The *two-dimensional echocardiogram* shows severe deformity of the pulmonary valve and right ventricular hypertrophy. In the late stages of the disease, dysfunction of the right ventricle is seen, and the ventricle may become dilated. Doppler studies demonstrate a large gradient (>60?mm Hg) across the pulmonary valve. Tricuspid regurgitation may also be prominent. Fortunately, the classic findings of severe pulmonary stenosis in older children are rarely seen because of early intervention. Signs of critical pulmonic stenosis are usually encountered in the neonatal period.

Figure 420.1-2 Roentgenogram in a patient with valvular pulmonary stenosis and a normal aortic root. The heart size is within normal limits, but poststenotic dilatation of the pulmonary artery is present.

Cardiac catheterization is not generally required for diagnostic purposes but is undertaken as part of a balloon valvuloplasty procedure. Catheterization demonstrates an abrupt pressure gradient across the pulmonary valve. Pulmonary artery pressure is either normal or low. The severity of the stenosis is based on right ventricular systolic pressure or the pressure gradient: a gradient of 10–30?mm Hg in mild cases, 30–60?mm Hg in moderate cases, and greater than 60?mm Hg or with right ventricular pressure greater than systemic pressure in severe cases. If cardiac output is low or a significant right-to-left shunt exists across the atrial septum, the pressure gradient may underestimate the degree of valve stenosis. *Selective right ventriculography* demonstrates the thickened, poorly mobile valve. In mild to moderate stenosis, doming of the valve in systole is readily seen. Flow of contrast medium through the stenotic valve in ventricular systole produces a narrow jet of dye that fills the dilated main pulmonary artery. Subvalvular hypertrophy that may intensify the obstruction may occasionally be present. The angiogram also indicates

whether the ventricular septum is intact.

Prognosis and Complications.

Heart failure occurs only in severe cases and most often during the 1st mo of life. The development of cyanosis from a right-to-left shunt across a foramen ovale is most often seen in infancy when the stenosis is severe. Infective endocarditis is a risk but is not common in childhood.

Children with mild stenosis can lead a normal life, but their progress should be evaluated at regular intervals. Patients who have small gradients rarely show progression and do not need intervention, but a more significant gradient is more likely to develop in children with moderate stenosis as they grow older. Worsening of obstruction may also be due to the development of secondary subvalvular muscular and fibrous tissue hypertrophy. In untreated severe stenosis, the course may abruptly worsen with the development of right ventricular dysfunction and cardiac failure. Infants with critical pulmonic stenosis require urgent catheter balloon valvuloplasty or surgical valvotomy.

Treatment.

Patients with moderate or severe isolated pulmonary stenosis require relief of the obstruction. Balloon valvuloplasty is the initial treatment of choice for the majority of patients (Fig. 420–3). Patients with severely thickened pulmonic valves, especially common in those with Noonan syndrome, may require surgical intervention instead. In a neonate with critical

Figure 420.1-3 Balloon pulmonary valvuloplasty. *A*, Hourglass shape of the balloon at the start of inflation. *B*, Full balloon inflation. The left pulmonary artery is protected from the sharp tip of the catheter with a flexibly tipped guide wire. (From Lababidi Z: Neonatal catheter palliations. In Long WA [editor]: *Fetal and Neonatal Cardiology*. Philadelphia, WB Saunders, 1990.)

pulmonic stenosis, urgent treatment by either balloon valvuloplasty or surgical valvotomy is warranted.

Excellent results are obtained in most instances. The gradient across the pulmonary valve is markedly reduced or abolished. In the early period after balloon valvuloplasty, a small to moderate residual gradient may remain because of muscular infundibular narrowing; it nearly always resolves with time. A short, early decrescendo diastolic murmur may be heard at the mid to upper left sternal border as a result of pulmonary valvular insufficiency. The degree of insufficiency is not usually clinically significant. No difference in patient status after valvuloplasty or surgery is noted at late follow-up; recurrence is unusual after successful treatment.

420.2 Infundibular Pulmonary Stenosis and Double-Chamber Right Ventricle

Infundibular pulmonary stenosis is caused by muscular or fibrous obstruction in the outflow tract of the right ventricle. The site of obstruction may be close to the pulmonary valve or well below it; an infundibular chamber may be present between the right ventricular cavity and the pulmonary valve. In many cases, a VSD may have been present initially and later closed spontaneously. When the pulmonary valve is also stenotic, the combined defect is primarily classified as valvular stenosis with secondary infundibular hypertrophy. The *hemodynamics* and *clinical manifestations* of patients with isolated infundibular pulmonary stenosis are similar, for the most part, to those described in the discussion of isolated valvular pulmonary stenosis (see Chapter 420.1).

A common variation in right ventricular outflow obstruction below the pulmonary valve is that of a double-chambered right ventricle. In this condition, a muscular band is present in the midright ventricular region; the band divides the chamber into two parts and creates obstruction between the inlet and outlet portions. An associated VSD that may close spontaneously is often noted. Obstruction is not usually seen early in life but may progress rapidly in a similar manner to the progressive infundibular obstruction observed with the tetralogy of Fallot (see Chapter 423.1).

The *diagnosis* of isolated right ventricular infundibular stenosis or double-chambered right ventricle can be made by echocardiography or cardiac catheterization and angiography, or by both. The ventricular septum must be evaluated carefully to determine whether an associated VSD is present. The prognosis for untreated cases of severe right ventricular outflow obstruction is similar to that for valvular pulmonary stenosis. When the obstruction is moderate to severe, surgery is indicated. After surgery, the pressure gradient is abolished or markedly reduced and the long-term outlook is excellent.

420.3 Pulmonary Stenosis in Combination with an Intracardiac Shunt

Valvular or infundibular pulmonary stenosis, or both, may be associated with either an ASD or a VSD. In these patients, the clinical features depend on the degree of pulmonary stenosis, which determines whether the net shunt is from left to right or from right to left.

The presence of a large left-to-right shunt at the atrial or ventricular level is evidence that the pulmonary stenosis is mild. These patients have symptoms similar to those of patients with an isolated ASD or VSD. However, with increasing age, worsening of the obstruction may limit the shunt and result in a gradual improvement in symptoms. Eventually, particularly in patients with pulmonary stenosis and VSD, a further increase in obstruction may lead to right-to-left shunting and cyanosis. When a patient with a VSD has evidence of decreasing heart failure and increased right ventricular forces on the electrocardiogram, one must differentiate between the development of increasing pulmonary stenosis and the onset of pulmonary vascular disease (Eisenmenger syndrome).

These anomalies are readily repaired surgically. Defects in the atrial or ventricular septum are closed, and the pulmonary stenosis is relieved by resection of

infundibular muscle or pulmonary valvotomy, or both, as indicated. Patients with a predominant right-to-left shunt have symptoms similar to those of patients with the tetralogy of Fallot (see Chapter 423.1).

420.4 Peri1pheral Pulmonary Stenosis

Single or multiple constrictions may occur anywhere along the major branches of the pulmonary arteries and may range from

mild to severe and from localized to extensive. Frequently, these defects are associated with other types of congenital heart disease, including valvular pulmonic stenosis, tetralogy of Fallot, patent ductus arteriosus (PDA), VSD, ASD, and supravalvular aortic stenosis. A familial tendency has been recognized in some patients with peripheral pulmonic stenosis. A high incidence is found in infants with congenital rubella syndrome. The combination of supravalvular aortic stenosis with pulmonary arterial branch stenosis, idiopathic hypercalcemia of infancy, elfin facies, and mental retardation is known as Williams syndrome, a condition associated with deletion of the elastin gene in region 7q11.23 on chromosome 7.

A mild constriction has little effect on the pulmonary circulation. With multiple severe constrictions, pressure is increased in the right ventricle and in the pulmonary artery proximal to the site of obstruction. When the anomaly is isolated, the *diagnosis* is suspected by the presence of murmurs in widespread locations over the chest, either anteriorly or posteriorly. These murmurs are usually systolic but may be continuous. Most often, the physical signs are dominated by the associated anomaly, such as the tetralogy of Fallot.

In the immediate newborn period, a mild and transient form of peripheral pulmonic stenosis may be present. Physical findings are generally limited to a soft systolic ejection murmur, which can be heard over either or both lung fields. It is the absence of other physical findings of valvular pulmonic stenosis (right ventricular lift, soft pulmonic 2nd sound, systolic ejection click, murmur loudest at the upper left sternal border) that supports this diagnosis. This murmur usually disappears by 1–2 mo.

If the stenosis is severe, the electrocardiogram shows evidence of right ventricular and right atrial hypertrophy, and the *chest radiograph* shows cardiomegaly and prominence of the main pulmonary artery. Generally, the pulmonary vasculature is normal; in some cases, however, small intrapulmonary vascular shadows are seen that represent areas of poststenotic dilatation. Echocardiography is limited in its ability to visualize the distal branch pulmonary arteries. Doppler examination demonstrates the acceleration of blood flow through the stenoses and, if tricuspid regurgitation is present, allows an estimation of right ventricular systolic pressure. MRI and CT are helpful in delineating distal obstructions; if moderate to severe disease is suspected, the diagnosis is usually confirmed by *cardiac catheterization*.

Severe obstruction of the main pulmonary artery and its primary branches can be relieved during corrective surgery for associated lesions such as the tetralogy of Fallot or valvular pulmonary stenosis. If peripheral pulmonic stenosis is isolated, it may be treated by catheter balloon dilatation. When peripheral obstruction occurs distally in the intrapulmonary vessels, it is not usually amenable to surgical repair. These obstructions are often multiple and are best treated with repeat balloon angioplasty, although the rate of recurrence is high. The introduction of expandable intravascular stents, placed by catheter in the distal pulmonary arteries and then dilated with a balloon to the appropriate size, may prevent re-stenosis.

420.5 Aortic Stenosis

Pathophysiology.

Congenital aortic stenosis accounts for about 5% of cardiac malformations recognized in childhood; a bicuspid aortic valve, one of the most common congenital heart lesions overall, is identified in up to 2% of adults and is usually asymptomatic in childhood. Aortic stenosis is more frequent in males (3:1). In the most common form, *valvular aortic stenosis*, the leaflets are thickened and the commissures are fused to varying degrees. Left ventricular systolic pressure is increased as a result of the obstruction to outflow. The ventricular wall hypertrophies in compensation; as its compliance decreases, end-diastolic pressure increases as well.

Subvalvular (subaortic) stenosis with a discrete fibromuscular shelf below the aortic valve is also an important form of left ventricular outflow tract obstruction. This lesion is frequently associated with other forms of congenital heart disease and may progress rapidly in severity. It is rarely diagnosed during early infancy and may develop despite previous documentation of no left ventricular outflow tract obstruction. Subvalvular aortic stenosis may become apparent after successful surgery for other congenital heart defects (e.g., coarctation of the aorta, PDA, VSD), may develop in association with mild lesions that have not been surgically repaired, or may occur as an isolated abnormality. Subvalvular aortic stenosis may also be due to a markedly hypertrophied ventricular septum, known as idiopathic hypertrophic subaortic stenosis or hypertrophic cardiomyopathy (see Chapter 431.2).

Supravalvular aortic stenosis, the least common type, may be sporadic, familial, or associated with Williams syndrome, which includes mental retardation, elfin facies (full face, broad forehead, flattened bridge of the nose, long upper lip, and rounded cheeks), and idiopathic hypercalcemia of infancy (see Chapter 70). Stenosis of other arteries, in particular, the branch pulmonary arteries, may also be present. Williams syndrome has been shown to be due to a deletion involving the elastin gene on chromosome 7q11.23.

Clinical Manifestations.

Symptoms in patients with aortic stenosis depend on the severity of the obstruction. Severe aortic stenosis that occurs in early infancy is termed *critical aortic stenosis* and is associated with left ventricular failure and signs of low cardiac output. Heart failure, cardiomegaly, and pulmonary edema are severe, the pulses are weak in all extremities, and the skin may be pale or grayish. Urine output may be diminished. If cardiac output is significantly decreased, the intensity of the murmur at the right upper sternal border may be minimal. Most children with less severe forms of aortic stenosis remain asymptomatic and display normal growth and development. The

murmur is usually discovered during routine physical examination. Rarely, fatigue, angina, dizziness, or syncope may develop in an older child with previously undiagnosed severe obstruction to left ventricular outflow. Sudden death has been reported with aortic stenosis but usually occurs in patients with severe left ventricular outflow obstruction in whom surgical relief has been delayed.

The physical findings are dependent on the degree of obstruction to left ventricular outflow. In mild stenosis, the pulses, heart size, and apical impulse are all normal. With increasing degrees of severity, the pulses become diminished in intensity and the heart may be enlarged, with a left ventricular apical thrust. Mild to moderate valvular aortic stenosis is usually associated with an early systolic ejection click, best heard at the apex and left sternal edge. Unlike the click in pulmonic stenosis, its intensity does not vary with respiration. Clicks are unusual in more severe aortic stenosis or in discrete subaortic stenosis. If the stenosis is severe, the 1st heart sound may be diminished because of decreased compliance of the thickened left ventricle. Normal splitting of the 2nd heart sound is present in mild to moderate obstruction. In patients with severe obstruction, the intensity of aortic valve closure is diminished, and rarely in children, the 2nd sound may be split paradoxically (becoming wider in expiration). A 4th heart sound may be audible when the obstruction is severe.

The intensity, pitch, and duration of the systolic ejection murmur are other indications of severity. Generally, the louder, harsher (higher pitch), and longer the murmur, the greater the degree of obstruction. The typical murmur is audible maximally at the right upper sternal border and radiates to the neck and the left midsternal border. It is usually accompanied by a thrill in the suprasternal notch. In patients with subvalvular aortic stenosis, the murmur may be maximal along the left sternal border or

---

even at the apex. A soft decrescendo diastolic murmur indicative of aortic insufficiency is often present when the obstruction is subvalvular or in patients with a bicuspid aortic valve. Occasionally, an apical short mid-diastolic rumbling murmur is audible, even in the presence of a normal mitral valve; however, this murmur should always raise suspicion of associated mitral valve stenosis.

Diagnosis.

The diagnosis can usually be made on the basis of the physical examination and the severity of obstruction confirmed by laboratory tests. If the pressure gradient across the aortic valve is mild, the *electrocardiogram* is likely to be normal. The electrocardiogram may occasionally be normal even with more severe obstruction, but evidence of left ventricular hypertrophy and strain (inverted T waves in the left precordial leads) is generally present if severe stenosis is long-standing. The *chest radiograph* frequently shows a prominent ascending aorta, but the aortic knob is normal. Heart size is typically normal. Valvular calcification has been noted only in older children and adults. *Echocardiography* identifies both the site and the severity of the obstruction. Two-dimensional imaging shows left ventricular hypertrophy, the thickened and domed aortic valve, the number of valve leaflets, and a subaortic or supra-aortic membrane, if present. Associated anomalies of the mitral valve or aortic arch or a VSD or PDA is present in up to 20% of cases. In the absence of left ventricular failure, the shortening fraction of the left ventricle may be increased because the ventricle is hypercontractile. In infants with critical aortic stenosis, the left ventricular shortening fraction is usually decreased and the endocardium may be bright, indicative of the development of endocardial fibrous scarring, known as **endocardial fibroelastosis**. Doppler studies show the specific site of obstruction and determine the peak and mean systolic left ventricular outflow tract gradients. When severe aortic obstruction is associated with left ventricular dysfunction, the Doppler-derived valve gradient may markedly underestimate the severity of the obstruction because of the low cardiac output.

Graded exercise testing is useful in evaluating the severity of left ventricular outflow tract obstruction in older children. As the severity of the gradient increases, working capacity decreases, systolic blood pressure fails to rise adequately, diastolic blood pressure may increase, and ST segment depression can occur. Because patients with severe aortic stenosis may deny symptoms and have normal electrocardiograms and chest roentgenograms, serial echocardiograms and graded exercise tests may be valuable in determining the timing of cardiac catheterization and surgical or balloon catheter valvuloplasty.

Left heart catheterization demonstrates the magnitude of the pressure gradient from the left ventricle to the aorta. The aortic pressure curve is abnormal if the obstruction is severe. In patients with severe obstruction and decreased left ventricular compliance, left atrial pressure is increased and pulmonary hypertension may be present. The site of obstruction is best identified by selective left ventriculography. Most infants with critical aortic stenosis do not require diagnostic cardiac catheterization but may undergo the procedure for balloon valvuloplasty. When a critically ill infant with left ventricular outflow tract obstruction undergoes cardiac catheterization, left ventricular function is often markedly decreased. As with the echocardiogram, the gradient measured across the stenotic aortic valve may underestimate the degree of obstruction because of low cardiac output. Actual measurement of cardiac output by thermodilution and calculation of the aortic valve area are helpful.

Prognosis.

Neonates with critical aortic stenosis may have severe heart failure and deteriorate rapidly to a low-output shock state. Emergency surgery or balloon valvuloplasty is lifesaving, but the mortality risk is not trivial. Neonates who die of critical aortic stenosis frequently have significant left ventricular endocardial fibroelastosis.

In older infants and children with mild to moderate aortic stenosis, the prognosis is reasonably good, although disease progression over a period of 5–10 yr is common. Patients with aortic valve gradients less than 40–50?mm Hg are considered to have mild disease; those with gradients of 40–70?mm Hg have moderate disease. These patients usually respond well to treatment (either surgery or valvuloplasty), although reoperations on the aortic valve are often required later in childhood or in adult life, and many patients eventually require valve replacement. In unoperated patients with severe obstruction, sudden death is a significant risk and often occurs during or immediately after exercise. Aortic stenosis is a common cause of sudden cardiac

death in the pediatric age group.

Patients with moderate to severe degrees of aortic stenosis should not participate in active competitive sports. In those with milder disease, sports participation is less severely restricted; however, patients should be encouraged to pursue less physically demanding activities. The status of each patient should be reviewed at least annually and intervention advised if progression of signs or symptoms occurs. Lifetime prophylaxis against infective endocarditis is required.

Treatment.

Balloon valvuloplasty is indicated for children with moderate to severe valvular aortic stenosis to prevent progressive left ventricular dysfunction and the risk of syncope and sudden death. It is generally agreed that valvuloplasty should be advised when the peak-to-peak systolic gradient between the left ventricle and aorta exceeds 60–70?mm Hg at rest, assuming normal cardiac output, or for lesser gradients when symptoms or electrocardiographic changes are present. For more rapidly progressive subaortic obstructive lesions, a gradient of 40–50?mm Hg is considered operable. Outside the neonatal period, surgical treatment is usually reserved for valves that are not amenable to balloon therapy, generally those that are extremely thickened.

In the neonatal period, balloon valvuloplasty is made somewhat more difficult by problems of arterial access. The risk of femoral arterial complications is much higher than in older children, although low-profile balloons have reduced this risk. Both surgical and catheter approaches are used at different centers for neonatal critical aortic stenosis.

Discrete *subaortic stenosis* can be resected without damage to the aortic valve, the anterior leaflet of the mitral valve, or the conduction system. This type of obstruction is not usually amenable to catheter treatment. Relief of *supravalvular stenosis* is also achieved surgically, and the results are excellent if the area of obstruction is discrete and not associated with a hypoplastic aorta. In association with supravalvular aortic stenosis, one or both coronary arteries may be stenotic at their origins because of a thick supra-aortic fibrous ridge. For patients who have aortic stenosis in association with severe tunnel-like subaortic obstruction, the left ventricular outflow tract can be enlarged by “borrowing” space anteriorly from the right ventricular outflow tract (the *Konno procedure*).

Regardless of whether surgical or catheter treatment has been carried out, aortic insufficiency or calcification with re-stenosis is likely to occur years or even decades later and eventually require reoperation and often aortic valve replacement. When recurrence develops, it may not be associated with early symptoms. Signs of recurrent stenosis include electrocardiographic signs of left ventricular hypertrophy, an increase in the Doppler echocardiographic gradient, deterioration in echocardiographic indices of left ventricular function, and recurrence of signs or symptoms during graded treadmill exercise. Evidence of significant aortic regurgitation includes symptoms of heart failure, cardiac enlargement on roentgenogram, and left ventricular dilatation on echocardiogram. The choice of reparative procedure depends on the relative degree of stenosis and regurgitation.

When aortic valve replacement is necessary, the choice of procedure often depends on the age of the patient. Homograft valves tend to calcify more rapidly in younger children, but they do not require chronic anticoagulation. Mechanical prosthetic valves are much longer lasting, yet they require anticoagulation, which can be difficult to manage in young children. In adolescent girls who are nearing childbearing age, consideration of the teratogenic effects of warfarin may warrant the use of a homograft valve. None of these options are perfect for a younger child who requires valve replacement because neither homograft nor mechanical valves grow with the patient. An alternative operation is aortopulmonary translocation, also known as the *Ross procedure*; it involves removing the patient's own pulmonary valve and using it to replace the abnormal aortic valve. A homograft is then placed in the pulmonary position. The advantage of this procedure is the potential for growth of the translocated living “neoaortic” valve and the longer longevity of the homograft valve when placed in the lower pressure pulmonary circulation. The long-term success of this operation, especially in young children, is being investigated. Tissue-engineered replacement valves grown in the laboratory from the patient's own arterial endothelial cells are under development in animal models.

420.6 Coarctation of the Aorta

Constrictions of the aorta of varying degrees may occur at any point from the transverse arch to the iliac bifurcation, but 98% occur just below the origin of the left subclavian artery at the origin of the ductus arteriosus (juxtaductal coarctation). The anomaly occurs twice as often in males as in females. Coarctation of the aorta may be a feature of Turner syndrome (see Chapters 70 and 580.1) and is associated with a bicuspid aortic valve in more than 70% of patients. Mitral valve abnormalities (a supravalvular mitral ring or parachute mitral valve) and subaortic stenosis are potential associated lesions. When this group of left-sided obstructive lesions occurs together, they are referred to as the *Shone complex*.

Pathophysiology.

Coarctation of the aorta can occur as a discrete juxtaductal obstruction or as tubular hypoplasia of the transverse aorta starting at one of the head or neck vessels and extending to the ductal area (preductal or infantile-type coarctation; Fig. 420–4). Often, both components are present. It is postulated that coarctation may be initiated in fetal life by the presence of a cardiac abnormality that results in decreased blood flow anterograde through the aortic valve (e.g., bicuspid aortic valve, VSD).

In patients with discrete juxtaductal coarctation, ascending aortic blood flows through the narrowed segment to reach the descending aorta, although left ventricular hypertension and hypertrophy result. In the 1st few days of life, the PDA may serve to widen the juxtaductal area of the aorta and provide temporary relief from the obstruction. Net left-to-right ductal shunting occurs in these acyanotic infants. With more severe juxtaductal coarctation or in the presence of transverse arch hypoplasia, right ventricular blood is ejected through the ductus to supply the descending aorta. Perfusion of the lower part of the body is then dependent on right ventricular output (see Fig. 420–4). In this situation, the femoral pulses are palpable,

and differential blood pressures may not be helpful in making the diagnosis. The ductal right-to-left shunting is manifested as differential cyanosis, with the upper extremities being pink and the lower extremities blue.

Such infants may have severe pulmonary hypertension and high pulmonary vascular resistance. Signs of heart failure are prominent. Occasionally, severely hypoplastic segments of the aortic isthmus may become completely atretic and result in an **interrupted aortic arch,** with the left subclavian artery arising either proximal or distal to the interruption. Coarctation associated

Figure 420.6-4 Metamorphosis of coarctation. *A*, Fetal prototype with no flow obstruction. *B*, Late gestation. The aortic ventricle increases its output and dilates the hypoplastic segment. Antegrade aortic flow bypasses the shelf via the ductal orifice. *C*, Neonate. Ductal constriction initiates the obstruction by removing the bypass and increasing antegrade arch flow. *D*, Mature juxtaductal stenosis. The bypass is completely obliterated, and intimal hypoplasia on the edge of the shelf is aggravating the stenosis. Collaterals develop. *E*, Persistence of the infantile-type fetal prototype. An intracardiac left-sided heart obstruction precludes an increase in antegrade aortic flow before or after birth. Both isthmus hypoplasia and a contraductal shelf are present. Lower body flow often depends on patency of the ductus. (From Gersony WM: Coarctation of the aorta. In Adams FH, Emmanouilides GC, Riemenshneider T [editors]: *Moss Heart Disease in Infants, Children, and Adolescents*, 4th ed. Baltimore, Williams & Wilkins, 1989.)

with arch hypoplasia was referred to as *infantile type* because its severity usually led to recognition of the condition in early infancy. *Adult type* referred to isolated juxtaductal coarctation, which if mild, was not usually recognized until later childhood. These terms have been replaced with the more accurate anatomic terms describing the location and severity of the defect.

Blood pressure is elevated in the vessels that arise proximal to the coarctation; blood pressure as well as pulse pressure is lower below the constriction. The hypertension is not due to the mechanical obstruction alone but also involves neurohumoral mechanisms. Unless operated on in infancy, coarctation of the aorta usually results in the development of an extensive collateral circulation, chiefly from branches of the subclavian, superior intercostal, and internal mammary arteries, to create channels for arterial blood to bypass the area of coarctation. The vessels contributing to the collateral circulation may become markedly enlarged and tortuous by early adulthood.

Clinical Manifestations.

Coarctation of the aorta recognized after infancy is rarely associated with significant symptoms. Some children or adolescents complain about weakness or pain (or both) in the legs after exercise, but in many instances, even patients with severe coarctation are asymptomatic. Older children are frequently brought to the cardiologist's attention when they are found to be hypertensive on routine physical examination.

The classic sign of coarctation of the aorta is a disparity in pulsation and blood pressure in the arms and legs. The femoral, popliteal, posterior tibial, and dorsalis pedis pulses are weak (or absent in up to 40% of patients), in contrast to the bounding

pulses of the arms and carotid vessels. The radial and femoral pulses should always be palpated simultaneously for the presence of a radial-femoral delay. Normally, the femoral pulse occurs slightly before the radial pulse. A radial-femoral delay occurs when blood flow to the descending aorta is dependent on collaterals, in which case the femoral pulse is felt after the radial pulse. In normal persons, systolic blood pressure in the legs obtained by the cuff method is 10–20?mm Hg higher than that in the arms. In coarctation of the aorta, blood pressure in the legs is lower than that in the arms; frequently, it is difficult to obtain. This differential in blood pressures is common in patients with coarctation who are older than 1 yr, about 90% of whom have systolic hypertension in an upper extremity greater than the 95th percentile for age. It is important to determine the blood pressure in each arm; a pressure higher in the right than the left arm suggests involvement of the left subclavian artery in the area of coarctation. Occasionally, the right subclavian may arise anomalously from below the area of coarctation and result in a left arm pressure that is higher than the right. With exercise, a more prominent rise in systemic blood pressure occurs, and the upper-to-lower extremity pressure gradient will increase.

The precordial impulse and heart sounds are usually normal; the presence of a systolic ejection click or thrill in the suprasternal notch suggests a bicuspid aortic valve (present in 70% of cases). A short systolic murmur is often heard along the left sternal border at the 3rd and 4th intercostal spaces. The murmur is well transmitted to the left infrascapular area and occasionally to the neck. Often, the typical murmur of mild aortic stenosis can be heard in the 3rd right intercostal space. Occasionally, more significant degrees of obstruction are noted across the aortic valve. The presence of a low-pitched mid-diastolic murmur at the apex suggests mitral valve stenosis. In older patients with well-developed collateral blood flow, systolic or continuous murmurs may be heard over the left and right sides of the chest laterally and posteriorly. In these patients, a palpable thrill can occasionally be appreciated in the intercostal spaces on the back.

Neonates or infants with more severe coarctation, usually including some degree of transverse arch hypoplasia, initially have signs of lower body hypoperfusion, acidosis, and severe heart failure. These signs may be delayed days or weeks until after closure of the ductus arteriosus. If detected before ductal closure, patients may exhibit differential cyanosis, best demonstrated by simultaneous oximetry of the upper and lower extremities. On physical examination, the heart is large, and a systolic murmur is heard along the left sternal border with a loud 2nd heart sound.

Diagnosis.

Findings on *roentgenographic examination* depend on the age of the patient and on the effects of hypertension and the collateral circulation. Cardiac enlargement and pulmonary congestion are noted in infants with severe coarctation. During childhood, the findings are not striking until after the 1st decade, when the heart tends to be mildly or moderately enlarged because of left ventricular prominence. The enlarged left subclavian artery commonly produces a prominent shadow in the left superior mediastinum. Notching of the inferior border of the ribs from pressure erosion by enlarged collateral vessels is common by late childhood. In most instances, the

descending aorta has an area of poststenotic dilatation.

The *electrocardiogram* is usually normal in young children but reveals evidence of left ventricular hypertrophy in older patients. Neonates and young infants display right or biventricular hypertrophy. The diagnosis can be made by careful evaluation of the pulses in all major accessible peripheral arteries and by comparative blood pressure determinations in the arms and legs. The segment of coarctation can generally be visualized by two-dimensional *echocardiography;* associated anomalies of the mitral and aortic valve can also be demonstrated. The descending aorta is hypopulsatile. Color Doppler is useful for demonstrating the specific site of the obstruction. Pulsed and continuous wave Doppler studies determine the pressure gradient directly at the area of coarctation; in the presence of a PDA, however, the severity of the narrowing may be underestimated. *Cardiac catheterization* with selective left ventriculography and aortography is useful in certain patients with additional anomalies and as a means of visualizing collateral blood flow. In cases that are well defined by echocardiography, diagnostic catheterization is not usually required before surgery.

Prognosis and Complications.

Abnormalities of the aortic valve are present in most patients. Bicuspid aortic valves are common but do not generally produce clinical signs unless the stenosis is significant. The association of a PDA and coarctation of the aorta is also common. VSDs and ASDs may be suspected by signs of a left-to-right shunt; they are exacerbated by the increased resistance to flow through the left side of the heart. Mitral valve abnormalities are also occasionally seen, as is subvalvular aortic stenosis.

Severe neurologic damage or even death may rarely occur from associated cerebrovascular disease. Subarachnoid or intracerebral hemorrhage may result from rupture of congenital aneurysms in the circle of Willis, rupture of other vessels with defective elastic and medial tissue, or rupture of normal vessels; these accidents are secondary to hypertension. Children with PHACE syndrome (*p*osterior brain fossa anomalies, facial *h*emangiomas, *a*rterial anomalies, *c*ardiac anomalies and aortic *c*oarctation, *e*ye anomalies) may have strokes (Table 415–1). Abnormalities of the subclavian arteries may include involvement of the left subclavian artery in the area of coarctation, stenosis of the orifice of the left subclavian artery, and anomalous origin of the right subclavian artery.

Untreated, the great majority of older patients with coarctation of the aorta would succumb between the ages of 20 and 40 yr; some live well into middle life without serious disability. The common serious complications are related to systemic hypertension, which may result in premature coronary artery disease, heart failure, hypertensive encephalopathy, or intracranial hemorrhage. Heart failure may be worsened by associated anomalies. Infective endocarditis or endarteritis is a significant complication in adults. Aneurysms of the descending aorta or the enlarged collateral vessels may develop. In infants with severe coarctation, heart failure and hypoperfusion may be life threatening and require immediate medical intervention.

Treatment.

In neonates with severe coarctation of the aorta, closure of the ductus often results in hypoperfusion, acidosis, and rapid deterioration. These patients should be given an infusion of prostaglandin E_1 to reopen the ductus and re-establish adequate lower extremity blood flow. Once a diagnosis has been confirmed and the patient stabilized, surgical repair should be performed. Older infants with heart failure but good perfusion should be managed with anticongestive measures to improve their clinical status before surgical intervention.

Older children with significant coarctation of the aorta should be treated relatively soon after diagnosis. Delay is unwarranted, especially after the 2nd decade of life, when the operation may be less successful because of decreased left ventricular function and degenerative changes in the aortic wall. Nevertheless, if cardiac reserve is sufficient, satisfactory repair is possible well into mid-adult life. Associated valvular lesions increase the hazards of late surgery.

The procedure of choice for isolated juxtaductal coarctation of the aorta is controversial. Surgery remains the treatment of choice, and several surgical techniques are used. The area of coarctation can be excised and a primary re-anastomosis performed. Often, the transverse aorta is splayed open and an "extended end-to-end" anastomosis performed to increase the effective cross-sectional area of the repair. The subclavian flap procedure, which involves division of the left subclavian artery

and incorporation of it into the wall of the repaired coarctation, is used by some, often in the younger age group. Others favor a patch aortoplasty, in which the area of coarctation is enlarged with a roof of prosthetic material. The use of angioplasty for native coarctation remains controversial.

After surgery, a striking increase in the amplitude of pulsations in the lower extremities is noted. In the immediate postoperative course, "rebound" hypertension is common and requires medical management. This exaggerated acute hypertension gradually subsides, and in most patients, antihypertensive medications can be discontinued. Residual murmurs are common and may be due to associated cardiac anomalies, to a residual flow disturbance across the repaired area, or to collateral blood flow. Rare operative problems include spinal cord injury from aortic cross-clamping if the collaterals are poorly developed, chylothorax, diaphragm injury, and laryngeal nerve injury. If a left subclavian flap is used, the radial pulse and blood pressure in the left arm are diminished or absent. Repair of coarctation in the 2nd decade of life or beyond may be associated with a higher incidence of premature cardiovascular disease, even in the absence of residual cardiac abnormalities. Early onset of adult chronic hypertension may occur, even in patients with adequately resected coarctation.

Although re-stenosis in older patients after coarctectomy is rare, a significant number of infants operated on before 1 yr of age require revision later in childhood. All patients should be monitored carefully for the development of recoarctation and aortic aneurysm. Should recoarctation occur, balloon angioplasty is the procedure of

choice. In these patients, scar tissue from previous surgery makes reoperation more difficult, yet makes balloon angioplasty safer because of the lower incidence of aneurysm formation. Relief of obstruction with this technique is usually excellent. Intravascular stents are now commonly used in many of these patients with generally excellent results.

Postcoarctectomy Syndrome.

Postoperative mesenteric arteritis may be associated with acute hypertension and abdominal pain in the immediate postoperative period. The pain varies in severity and may occur in conjunction with anorexia, nausea, vomiting, leukocytosis, intestinal hemorrhage, bowel necrosis, and small bowel obstruction. Relief is usually obtained with antihypertensive drugs (nitroprusside, esmolol, captopril) and intestinal decompression; rarely, surgical exploration is required for bowel obstruction or infarction.

420.7 Coarctation with Ventricular Septal Defect

Coarctation in the presence of VSD results in both increased preload and afterload on the left ventricle, and patients with this combination of defects will be recognized either at birth or in the 1st mo of life and often have intractable cardiac failure. The magnitude of a left-to-right shunt through a VSD is dependent on the ratio of pulmonary to systemic vascular resistance. In the presence of coarctation, resistance to systemic outflow is enhanced by the obstruction, and the volume of the shunt is markedly increased. The clinical picture is that of a seriously ill infant with tachypnea, failure to thrive, and typical findings of heart failure. Often, the difference in blood pressure between the upper and lower extremities is not very marked because cardiac output may be low. Although medical management may be helpful initially, early surgical repair is necessary.

In most cases, coarctation is the major anomaly causing the severe symptoms, and resection of the coarctated segment results in striking improvement. Some repair the coarctation through a left lateral thoracotomy and at the same time place a pulmonary artery band to decrease the ventricular-level shunt. Some do not band the pulmonary artery initially because a number of patients improve sufficiently so that further surgery is not required during early infancy. If heart failure makes it difficult to manage these infants after surgery, open repair of the VSD is then performed soon thereafter. Others routinely repair both the VSD and coarctation at the same operation through a midline sternotomy. When it is determined that a complicated VSD is present (multiple VSDs, apical muscular VSD), pulmonary arterial banding may be performed at the time of coarctation repair to avoid open heart surgery during infancy for these complex ventricular septal abnormalities.

420.8 Coarctation with Other Cardiac Anomalies and Interrupted Aortic Arch

Coarctation often occurs in infancy in association with other major cardiovascular anomalies, including hypoplastic left heart, severe mitral or aortic valve disease, transposition of the great arteries, and variations of double-outlet or single ventricle. Severe coarctation may also be associated with endocardial fibroelastosis. The clinical manifestations depend on the effects of the associated malformations, as well as on the coarctation itself.

Coarctation of the aorta associated with severe mitral and aortic valve disease may have to be treated within the context of the hypoplastic left heart syndrome (see Chapter 424.10), even if the left ventricular chamber is not severely hypoplastic. Such patients usually have a long segment of narrow transverse aortic arch with or without an isolated coarctation at the site of the ductus arteriosus. Coarctation of the aorta with transposition of the great arteries or single ventricle may be repaired alone or in combination with other palliative measures.

Complete interruption of the aortic arch is the most severe form of coarctation and is usually associated with other intracardiac pathology. Interruption may occur at any level, although it is most commonly seen between the left subclavian artery and the insertion of the ductus arteriosus. In newborns with an interrupted aortic arch, the ductus arteriosus provides the sole source of blood flow to the descending aorta, and differential oxygen saturation between the right arm (normal saturation) and the legs (decreased) can be noted. When the ductus begins to close, severe congestive heart failure, lower extremity hypoperfusion, anuria, and shock can develop in these infants. Patients with an interrupted aortic arch can be supported with prostaglandin to keep the ductus patent before surgical repair. As one of the conotruncal malformations, an interrupted aortic arch can be associated with the spectrum of lesions known as CATCH 22 (*c*ardiac defects, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, *h*ypocalcemia). CATCH 22 includes patients with clinical features of the *DiGeorge syndrome* (hypocalcemia, thymic hypoplasia, mild facial anomalies) and the *Shprintzen velocardiofacial syndrome* (abnormal facies, cleft palate). Cytogenetic analysis using fluorescence in situ hybridization demonstrates deletions of a segment of chromosome 22q11 known as the DiGeorge critical region.

420.9 Congenital Mitral Stenosis

Congenital mitral stenosis is a rare anomaly that can be isolated or associated with other defects, the most common being aortic stenosis and coarctation of the aorta. The mitral valve may be funnel-shaped, with thickened leaflets and chordae tendineae that are shortened and deformed. Other mitral valve anomalies associated with stenosis include *parachute mitral valve*, caused by a single papillary muscle, and *double-orifice mitral valve*.

Symptoms usually appear within the 1st 2 yr of life. These infants are underdeveloped and generally have obvious dyspnea

secondary to heart failure; cyanosis and pallor are common. In some patients whose symptoms are mainly wheezing, reactive airway disease may have been diagnosed. Heart enlargement as a result of dilatation and hypertrophy of the right ventricle and left atrium is common. Most patients have rumbling apical diastolic murmurs followed by a loud 1st sound, but the auscultatory findings may be relatively obscure. The 2nd sound is loud and split. An opening snap of the mitral valve may be present. The *electrocardiogram* reveals right ventricular hypertrophy with normal, bifid, or spiked P waves indicative of left atrial enlargement. *Roentgenograms* usually show left atrial

and right ventricular enlargement and pulmonary congestion. The *echocardiogram* is characteristic and shows thickened mitral valve leaflets, a diminished E-F slope on the M-mode mitral echocardiogram, and an enlarged left atrium with a normal or small left ventricle. Two-dimensional echocardiographic examination shows a significant reduction of the mitral valve orifice in diastole. Doppler studies demonstrate a mean pressure gradient across the mitral orifice. At *cardiac catheterization*, an increase in right ventricular, pulmonary arterial, and pulmonary capillary wedge pressure can be noted. Associated anomalies such as aortic stenosis and coarctation are demonstrated. *Angiocardiography* shows delayed emptying of the left atrium and the small mitral orifice.

The prognosis for untreated patients is poor. The results of surgical treatment have been mixed; a mitral valve prosthesis is usually required, but it must be replaced as the child grows. These patients must be managed by anticoagulation with warfarin, and complications of excessive and insufficient anticoagulation are fairly common in infancy. Transcatheter balloon valvuloplasty has been used by several centers as a palliative procedure with mixed results, depending on the anatomy of the valve and the papillary muscles.

420.10 Pulmonary Venous Hypertension

A variety of lesions may give rise to chronic pulmonary venous hypertension, which when extreme may result in pulmonary arterial hypertension and right-sided heart failure. These lesions include congenital mitral stenosis, mitral insufficiency, total anomalous pulmonary venous return with obstruction, left atrial myxomas, cor triatriatum (stenosis of a common pulmonary vein), individual pulmonary vein stenosis, and supravalvular mitral rings or webs. Early symptoms can be confused with chronic pulmonary disease such as asthma because of a lack of specific cardiac findings on physical examination. Subtle signs of pulmonary hypertension may be present. The *electrocardiogram* shows right ventricular hypertrophy with spiked P waves. *Roentgenographic studies* reveal cardiac enlargement and prominence of the pulmonary veins in the hilar region, the right ventricle and atrium, and the main pulmonary artery; the left atrium is normal in size or only slightly enlarged.

The *echocardiogram* may demonstrate left atrial myxoma, cor triatriatum, or mitral valve abnormality. *Cardiac catheterization* excludes the presence of a shunt and demonstrates pulmonary hypertension with elevated pulmonary arterial wedge pressure. Left atrial pressure is normal if the lesion is at the level of the pulmonary veins, but it is elevated if the lesion is at the level of the mitral valve. Selective pulmonary arteriography usually delineates the anatomic lesion. Cor triatriatum, left atrial myxoma, and supravalvular mitral webs can all be successfully managed surgically.

The differential diagnosis includes *pulmonary veno-occlusive disease*, an idiopathic process that produces obstructive lesions in the pulmonary veins of children and young adults. The cause is uncertain. The patient is initially thought to have left-sided heart failure on the basis of congested lungs with apparent pulmonary edema. Dyspnea, fatigue, and pleural effusions are common; cyanosis, digital clubbing, syncope, and hemoptysis are variable findings. Left atrial pressure is normal, but pulmonary arterial wedge pressure is usually elevated. A normal wedge pressure may be encountered if collaterals have formed or the wedge recording is performed in an uninvolved segment. Angiographically, the pulmonary veins return normally to the left atrium, but one or more pulmonary veins are narrowed, either focally or diffusely.

Lung biopsy demonstrates pulmonary venous and, occasionally, arterial involvement. Pulmonary veins and venules demonstrate fibrous narrowing or occlusion, and pulmonary artery thrombi may be present. Therapy is disappointing, and survival ranges from weeks to months in infants and from months to years in adults. Attempts at surgical repair, balloon dilatation, and transcatheter stenting have not significantly improved the prognosis of these patients. Combined heart-lung transplantation (see Chapter 435.2) remains the only moderately successful therapeutic option.

Chapter 421 - Acyanotic Congenital Heart Disease: Regurgitant Lesions

421.1 Pulmonary Valvular Insufficiency and Congenital Absence of the Pulmonary Valve

Pulmonary valvular insufficiency most often accompanies other cardiovascular diseases or may be secondary to severe pulmonary hypertension. Incompetence of the valve is an expected result after surgery for right ventricular outflow tract obstruction—for example, pulmonary valvotomy in patients with valvular pulmonic stenosis or valvotomy with infundibular resection in patients with the tetralogy of Fallot. Isolated congenital insufficiency of the pulmonary valve is rare. These patients are usually asymptomatic because the insufficiency is generally mild.

The prominent physical sign is a decrescendo diastolic murmur at the upper and midleft sternal border, which has a lower pitch than the murmur of aortic insufficiency because of the lower pressure involved. Roentgenograms of the chest show prominence of the main pulmonary artery and, if the insufficiency is severe, right ventricular enlargement. The electrocardiogram is normal or shows minimal right ventricular hypertrophy. Pulsed and color Doppler studies demonstrate retrograde flow from the pulmonary artery to the right ventricle during diastole. The diagnosis can be made at cardiac catheterization if necessary. Pulmonary arterial diastolic pressure is low. Selective pulmonary arteriography shows the incompetent valve, but it is difficult to evaluate in mild cases because the catheter crossing the valve usually results in some iatrogenic insufficiency during the injection. Isolated pulmonary valvular incompetence is generally well tolerated and does not require surgical treatment. When pulmonary insufficiency is severe, especially if significant tricuspid insufficiency is also present, replacement with a homograft may become necessary to preserve right ventricular function.

Congenital absence of the pulmonary valve is usually associated with a ventricular septal defect, often in the context of the tetralogy of Fallot (see Chapter 423.1). In many of these neonates, the pulmonary arteries become widely dilated and compress the bronchi, with subsequent recurrent episodes of wheezing, pulmonary collapse, and pneumonitis. The presence and degree of cyanosis are variable. Florid pulmonary valvular incompetence may not be well tolerated, and death may occur from a combination of bronchial compression, hypoxemia, and heart failure. Correction involves plication of the massively dilated pulmonary arteries, closure of the ventricular septal defect, and placement of a homograft across the right

ventricular outflow tract.

421.2 Congenital Mitral Insufficiency

Congenital mitral insufficiency may be isolated but is more often associated with other anomalies, including patent ductus arteriosus, coarctation of the aorta, ventricular septal defect, corrected transposition of the great vessels, anomalous origin of the left coronary artery from the pulmonary artery, or Marfan syndrome. Mitral insufficiency is common in patients with atrioventricular septal defects (see Chapter 419.5). Mitral insufficiency can also be seen in patients with cardiomyopathy and severe left ventricular dysfunction secondary to dilatation of the valve ring.

In isolated mitral insufficiency, the mitral valve annulus is usually dilated, the chordae tendineae are short and may insert anomalously, and the valve leaflets are deformed. When mitral insufficiency is severe enough to cause clinical symptoms, the left atrium enlarges as a result of the regurgitant flow, and the left ventricle becomes hypertrophied and dilated. Pulmonary venous pressure is increased, and the increased pressure ultimately results in pulmonary hypertension and right ventricular hypertrophy and dilatation. Mild lesions produce no symptoms; the only abnormal sign is the holosystolic murmur of mitral incompetence. Severe regurgitation results in symptoms that can appear at any age, including poor physical development, frequent respiratory infections, fatigue on exertion, and episodes of pulmonary edema or congestive heart failure. Often, a diagnosis of reactive airway disease will have been made because of the similarity in pulmonary symptoms.

The typical murmur of mitral insufficiency is a high-pitched (often referred to as a “cooing dove”), apical holosystolic murmur. If the insufficiency is moderate to severe, it is usually associated with an apical low-pitched, mid-diastolic rumbling murmur indicative of increased diastolic flow across the mitral valve. The pulmonary component of the 2nd heart sound will be accentuated in the presence of pulmonary hypertension. The electrocardiogram usually shows bifid P waves, signs of left ventricular hypertrophy, and sometimes signs of right ventricular hypertrophy. Roentgenographic examination shows enlargement of the left atrium, which at times is massive. The left ventricle is prominent, and pulmonary vascularity is normal or prominent. The echocardiogram demonstrates the enlarged left atrium and ventricle. Color Doppler demonstrates the extent of insufficiency, and pulsed Doppler of the pulmonary veins detects retrograde flow when mitral insufficiency is severe. Cardiac catheterization shows elevated left atrial pressure. Pulmonary artery hypertension of varying severity may be present. Selective left ventriculography reveals the severity of mitral regurgitation.

Mitral valvuloplasty can result in striking improvement in symptoms and heart size, but in some patients, installation of a prosthetic mechanical mitral valve may be necessary. Before surgery, associated anomalies must be identified. In children beyond 3–4 yr, it may be difficult to exclude rheumatic fever as the cause of mitral insufficiency.

421.3 Mitral Valve Prolapse

Mitral valve prolapse results from an abnormal mitral valve mechanism that causes billowing of one or both mitral leaflets, especially the posterior cusp, into the left atrium toward the end of systole. The abnormality is predominantly congenital but may not be recognized until adolescence or adulthood. Mitral valve prolapse is more common in girls and may be inherited as an autosomal dominant trait with variable expression. It is common in patients with Marfan syndrome, straight back syndrome, pectus excavatum, and scoliosis. The dominant abnormal signs are auscultatory, although occasional patients may have chest pain or palpitations. The apical murmur is late systolic and may be preceded by a click, but these signs may vary in the same patient, and at times only the click is audible. In the standing or sitting position the click may appear earlier in systole, and the murmur may be more prominent in late systole. Arrhythmias may occur and are primarily unifocal or multifocal premature ventricular contractions.

The electrocardiogram is usually normal but may show biphasic T waves, especially in leads II, III, aVF, and V_6 ; the T-wave abnormalities may vary at different times in the same patient. The chest roentgenogram is normal. The echocardiogram shows a characteristic posterior movement of the posterior mitral leaflet during mid or late systole or demonstrates pansystolic prolapse of both the anterior and posterior mitral leaflets. These M-mode echocardiographic findings must be interpreted cautiously because the appearance of minimal mitral prolapse may be a normal variant. Two-dimensional real-time echocardiography shows that both the free edge and the body of the mitral leaflets move posteriorly in systole toward the left atrium. The presence and severity of mitral regurgitation can be assessed by Doppler.

This lesion is not progressive in childhood, and specific therapy is not indicated. The patient may be at risk for the development of infective endocarditis. Antibiotic prophylaxis is recommended during surgery and dental procedures (see Chapter 429).

Adults (men more often than women) with mitral valve prolapse are at increased risk for cardiovascular complications (sudden death, arrhythmia, cerebrovascular accidents, progressive valve dilatation, heart failure, and endocarditis) in the presence of thickened and redundant mitral valve leaflets.

Often, confusion exists concerning the diagnosis of mitral valve prolapse. The high frequency of mild prolapse on the echocardiogram in the absence of clinical findings suggests that in these cases true mitral valve prolapse syndrome is not present. These patients and their parents should be reassured of this fact, and no special recommendations should be made regarding management or frequent laboratory studies. Endocarditis prophylaxis is indicated only in substantiated cases, usually those with mitral insufficiency.

421.4 Tricuspid Regurgitation

Isolated tricuspid regurgitation is generally associated with Ebstein anomaly of the tricuspid valve. Ebstein anomaly may occur either without cyanosis or with varying degrees of cyanosis, depending on the severity of the tricuspid regurgitation and the presence of an atrial-level communication (patent foramen ovale or atrial septal

defect). Older children tend to have the acyanotic form, whereas if detected in the newborn period, Ebstein anomaly is usually associated with severe cyanosis (see Chapter 423.7c).

Tricuspid regurgitation often accompanies right ventricular dysfunction. When the right ventricle becomes dilated because of volume overload or intrinsic myocardial disease, or both, the tricuspid annulus also enlarges, with resultant valve insufficiency. This form of regurgitation may improve if the cause of the right ventricular dilatation is corrected, or it may require surgical plication of the valve annulus. Tricuspid regurgitation is also encountered in newborns with perinatal asphyxia. The cause may be related to an increased susceptibility of the papillary muscles to ischemic damage and subsequent transient papillary muscle dysfunction.

Chapter 422 - Cyanotic Congenital Heart Disease: Evaluation of the Critically Ill Neonate with Cyanosis and Respiratory Distress

See also Chapter 90 .

A severely ill neonate with cardiorespiratory distress and cyanosis is a diagnostic challenge. The clinician must perform a rapid evaluation to determine whether congenital heart disease is a cause so that potentially lifesaving measures can be instituted. The differential diagnosis of neonatal cyanosis is presented in Table 90–1 .

Cardiac Disease.

Congenital heart disease produces cyanosis when obstruction to right ventricular outflow causes intracardiac right-to-left shunting or when complex anatomic defects, unassociated with pulmonary stenosis, cause an admixture of pulmonary and systemic venous return in the heart. Cyanosis from pulmonary edema may also develop in patients with heart failure caused by left-to-right shunts, although the degree is usually less severe. Cyanosis may be caused by persistence of fetal pathways, for example, right-to-left shunting across the foramen ovale and ductus arteriosus in the presence of pulmonary outflow tract obstruction or persistent pulmonary hypertension of the newborn (PPHN) (see Chapter 93.7).

Differential Diagnosis.

The initial evaluation of a cyanotic infant begins with observation of the breathing pattern. Weak or irregular respiration is often associated with a weak sucking reflex and a central nervous system (CNS) problem. Convulsions and general depression strongly suggest a CNS cause. An infant with primary cardiac or pulmonary disease, in contrast, displays vigorous or labored respirations with tachypnea.

The *hyperoxia* test is one method of distinguishing cyanotic congenital heart disease from pulmonary disease. Neonates with cyanotic congenital heart disease usually do not have significantly raised arterial Pa_{O_2} during administration of 100% oxygen. If the Pa_{O_2} rises above 150?mm?Hg during 100% oxygen administration, an intracardiac shunt can usually be excluded, although the Pa_{O_2} of some patients with cyanotic congenital heart lesions may be transiently increased to greater than 150?mm?Hg because of intracardiac streaming patterns. The Pa_{O_2} in patients with pulmonary disease generally increases significantly as ventilation-perfusion inequalities are

overcome by oxygen administration. In infants with a CNS disorder, the Pa_{O_2} completely normalizes during artificial ventilation. Hypoxia in many heart lesions is profound and constant, whereas in respiratory disorders and in primary hypertension of the neonate (PPHN), arterial oxygen tension is not as low and often varies with time or changes in ventilator management. Hyperventilation may improve the hypoxia in neonates with PPHN and only occasionally in those with cyanotic heart disease.

Although a significant heart murmur usually suggests a cardiac basis for the cyanosis, several of the more severe cardiac defects (transposition of the great vessels) may not initially be associated with a murmur. The chest roentgenogram may be helpful in the differentiation of pulmonary and cardiac disease; in the latter, it indicates whether pulmonary blood flow is increased, normal, or decreased.

Two-dimensional echocardiography is the definitive noninvasive test to determine the presence of congenital heart disease. The information obtained is essential in avoiding unnecessary cardiac catheterization and angiography in the absence of a cardiac defect, as well as in making a specific diagnosis. If echocardiography is not immediately available, the clinician caring for a newborn with possible cyanotic heart disease should not hesitate to start a prostaglandin infusion (for a possible ductal-dependent lesion). Because of the risk of hypoventilation associated with prostaglandins, a practitioner skilled in neonatal endotracheal intubation must be available.

Chapter 423 - Cyanotic Congenital Heart Lesions: Lesions Associated with Decreased Pulmonary Blood Flow

423.1 Tetralogy of Fallot

The tetralogy of Fallot consists of (1) obstruction to right ventricular outflow (pulmonary stenosis), (2) ventricular septal defect (VSD), (3) dextroposition of the aorta with septal override, and (4) right ventricular hypertrophy (Fig. 423–1). Obstruction to pulmonary arterial blood flow is usually at both the right ventricular infundibulum (subpulmonic area) and the pulmonary valve. The main pulmonary artery is often small, and various degrees of branch pulmonary artery stenosis may be present. Complete obstruction of right ventricular outflow *(pulmonary atresia with VSD)* is classified as an extreme form of tetralogy of Fallot.

Pathophysiology.

The pulmonary valve annulus may be of nearly normal size or quite small. The valve itself is often bicuspid and, occasionally, is the only site of stenosis. More commonly, the subpulmonic muscle, the crista supraventricularis, is hypertrophic, which contributes to the infundibular stenosis and results in an infundibular chamber of variable size and contour. When the right ventricular outflow tract is completely obstructed (pulmonary atresia), the anatomy of the branch pulmonary arteries is extremely variable; a main pulmonary artery segment may be in continuity with right ventricular outflow, separated by a fibrous but imperforate pulmonary valve, or the entire main pulmonary artery segment may be absent. Occasionally, the branch pulmonary arteries may be discontinuous. In these more severe cases, pulmonary blood flow may be supplied by a patent ductus arteriosus (PDA) and by *major aortopulmonary collateral arteries (MAPCAs)* arising from the aorta.

The VSD is usually nonrestrictive and large, is located just below the aortic valve, and is related to the posterior and right aortic cusps. Rarely, the VSD may be in the inlet portion of the ventricular septum (atrioventricular septal defect). The normal fibrous continuity of the mitral and aortic valves is usually maintained. The aortic arch is right sided in 20%, and the aortic root is usually large and overrides the VSD to a varying degree. When the aorta overrides the VSD more than 50% and if muscle is significantly separating the aortic valve and the mitral annulus (subaortic conus), this defect is usually classified as a form of *double-outlet right ventricle;* the pathophysiology is the same as that for tetralogy of Fallot.

Figure 423.1-1 Physiology of the tetralogy of Fallot. *Circled numbers* represent oxygen saturation values. The numbers next to the arrows represent volumes of blood flow (in L/min/m^2). Atrial (mixed venous) oxygen saturation is decreased because of the systemic hypoxemia. A volume of 3 L/min/m^2 of desaturated blood enters the right atrium and traverses the tricuspid valve. Two liters flows through the right ventricular outflow tract into the lungs, whereas 1?L shunts right to left through the ventricular septal defect (VSD) into the ascending aorta. Thus, pulmonary blood flow is two thirds normal (Qp:Qs of 0.7:1). Blood returning to the left atrium is fully saturated. Only 2?L of blood flows across the mitral valve. Oxygen saturation in the left ventricle may be slightly decreased because of right-to-left shunting across the VSD. Two liters of saturated left ventricular blood mixing with 1?L of desaturated right ventricular blood is ejected into the ascending aorta. Aortic saturation is decreased, and cardiac output is normal.

Systemic venous return to the right atrium and right ventricle is normal. When the right ventricle contracts in the presence of marked pulmonary stenosis, blood is shunted across the VSD into the aorta. Persistent arterial desaturation and cyanosis result. Pulmonary blood flow, when severely restricted by the obstruction to right ventricular outflow, may be supplemented by the bronchial collateral circulation (MAPCAs) and, in the newborn, by a PDA. Peak systolic and diastolic pressures in each ventricle are similar and at the systemic level. A large pressure gradient occurs across the obstructed right ventricular outflow tract, and pulmonary arterial pressure is normal or lower than normal. The degree of right ventricular outflow obstruction determines the timing of the onset of symptoms, the severity of cyanosis, and the degree of right ventricular hypertrophy. When obstruction to right ventricular outflow is mild to moderate and a balanced shunt is present across the VSD, the patient may not be visibly cyanotic *(acyanotic or “pink” tetralogy of Fallot)*.

Clinical Manifestations.

Infants with mild degrees of right ventricular outflow obstruction may initially be seen with heart failure caused by a ventricular-level left-to-right shunt. Often, cyanosis is not present at birth, but with increasing hypertrophy of the right ventricular infundibulum and patient growth, cyanosis occurs later in the 1st yr of life. It is most prominent in the mucous membranes of the lips and mouth and in the fingernails and toenails. In infants with severe degrees of right ventricular outflow obstruction, neonatal cyanosis is noted immediately. In

these infants, pulmonary blood flow may be dependent on flow through the ductus arteriosus. When the ductus begins to close in the 1st few hours or days of life, severe cyanosis and circulatory collapse may occur. Older children with long-standing cyanosis who have not undergone surgery may have dusky blue skin, gray sclerae with engorged blood vessels, and marked *clubbing* of the fingers and toes. Extracardiac manifestations of long-standing cyanotic congenital heart disease are described in Chapter 427 .

Dyspnea occurs on exertion. Infants and toddlers play actively for a short time and then sit or lie down. Older children may be able to walk a block or so before stopping to rest. Characteristically, children assume a *squatting* position for the relief of dyspnea caused by physical effort; the child is usually able to resume physical activity within a few minutes. These findings occur most often in patients with significant cyanosis at rest.

Paroxysmal hypercyanotic attacks (hypoxic, “blue,” or “tet” spells) are a particular problem during the 1st 2 yr of life. The infant becomes hyperpneic and restless, cyanosis increases, gasping respirations ensue, and syncope may follow. The spells occur most frequently in the morning on initially awakening or after episodes of vigorous crying. Temporary disappearance or a decrease in intensity of the systolic murmur is usual as flow across the right ventricular outflow tract diminishes. The spells may last from a few minutes to a few hours but are rarely fatal. Short episodes are followed by generalized weakness and sleep. Severe spells may progress to unconsciousness and, occasionally, to convulsions or hemiparesis. The onset is usually spontaneous and unpredictable. Spells are associated with reduction of an already compromised pulmonary blood flow, which when prolonged results in severe systemic hypoxia and metabolic acidosis. Infants who are only mildly cyanotic at rest are often more prone to the development of hypoxic spells because they have not acquired the homeostatic mechanisms to tolerate rapid lowering of arterial oxygen saturation, such as polycythemia.

Depending on the frequency and severity of hypercyanotic attacks, one or more of the following procedures should be instituted in sequence: (1) placement of the infant on the abdomen in the knee-chest position while making certain that the infant's clothing is not constrictive, (2) administration of oxygen (although increasing inspired oxygen will not reverse cyanosis caused by intracardiac shunting), and (3) injection of morphine subcutaneously in a dose not in excess of 0.2?mg/kg. Calming and holding the infant in a knee-chest position may abort progression of an early spell. Premature attempts to obtain blood samples may cause further agitation and be counterproductive.

Because metabolic acidosis develops when arterial P_{O_2} is less than 40?mm Hg, rapid correction (within several minutes) with intravenous administration of sodium bicarbonate is necessary if the spell is unusually severe and the child shows a lack of response to the foregoing therapy. Recovery from the spell is usually rapid once the pH has returned to normal. Repeated blood pH measurements may be necessary because rapid recurrence of acidosis may ensue. For spells that are resistant to this therapy, drugs that increase systemic vascular resistance, such as intravenous methoxamine or phenylephrine, improve right ventricular outflow, decrease the right-to-left shunt, and thus improve the symptoms. ß-Adrenergic blockade by the intravenous administration of propranolol (0.1?mg/kg given slowly to a maximum of 0.2?mg/kg) is also useful.

Growth and development may be delayed in patients with severe untreated tetralogy of Fallot, particularly when oxygen saturation is chronically less than 70%. Puberty may also be delayed in patients who do not undergo surgery.

The pulse is usually normal, as is venous and arterial pressure. The left anterior hemithorax may bulge anteriorly because of right ventricular hypertrophy. The heart is generally normal in size, and a *substernal right ventricular impulse* can be detected. In about half the cases, a *systolic thrill* is felt along the left sternal border in the 3rd and 4th parasternal spaces. The *systolic murmur* is usually loud and harsh; it may be transmitted widely, especially to the lungs, but is most intense at the left

sternal border. The murmur is generally ejection in quality at the upper sternal border, but it may sound more holosystolic toward the lower sternal border. It may be preceded by a click. The murmur is caused by turbulence through the right ventricular outflow tract. It tends to become louder, longer, and harsher as the severity of pulmonary stenosis increases from mild to moderate; however, it can actually become less prominent with severe obstruction, especially during a hypercyanotic spell. Either the 2nd heart sound is single, or the pulmonic component is soft. Infrequently, a continuous murmur may be audible, especially if prominent collaterals are present.

Diagnosis.

Roentgenographically, the typical configuration as seen in the anteroposterior view consists of a narrow base, concavity of the left heart border in the area usually occupied by the pulmonary artery, and normal heart size. The hypertrophied right ventricle causes the rounded apical shadow to be up-tilted so that it is situated higher above the diaphragm than normal. The cardiac silhouette has been likened to that of a boot or wooden shoe *(coeur en sabot)* (Fig. 423–2). The hilar areas and lung fields are relatively clear because of diminished pulmonary blood flow or the small size of the pulmonary arteries, or both. The aorta is usually large, and in about 20% of instances it arches to the right, which results in an indentation of the leftward-positioned air-filled tracheobronchial shadow in the anteroposterior view.

The *electrocardiogram* demonstrates right axis deviation and evidence of right ventricular hypertrophy. A dominant R wave appears in the right precordial chest leads (Rs, R, qR, qRs) or an RSR¢ pattern. In some cases, the only sign of right ventricular hypertrophy may initially be a positive T wave in leads V_3 R and V_1 . The P wave is tall and peaked or sometimes bifid (see Fig. 416–8).

Two-dimensional echocardiography establishes the diagnosis (Fig. 423–3) and provides information about the extent of aortic override of the septum, the location and degree of the right ventricular outflow tract obstruction, the size of the proximal branch pulmonary arteries, and the side of the aortic arch. The echocardiogram is also useful in determining whether a PDA is supplying a portion of the pulmonary blood flow. It may obviate the need for catheterization.

Figure 423.1-2 Roentgenogram of an 8-yr-old boy with the tetralogy of Fallot. Note the normal heart size, some elevation of the cardiac apex, concavity in the region of the main pulmonary artery, right-sided aortic arch, and diminished pulmonary vascularity.

Figure 423.1-3 Echocardiogram in a patient with the tetralogy of Fallot. This short-axis, subxiphoid, two-dimensional echocardiographic projection demonstrates anterior/superior displacement of the outflow ventricular septum that resulted in stenosis of the subpulmonic right ventricular outflow tract and an associated anterior ventricular septal defect (VSD). RV = right ventricle; AO = overriding aortic valve; LV = left ventricle.

Cardiac catheterization demonstrates a systolic pressure in the right ventricle equal to systemic pressure. If the pulmonary artery is entered, the pressure is markedly decreased, although crossing the right ventricular outflow tract, especially in severe cases, may precipitate a tet spell. Pulmonary arterial pressure is usually lower than normal, in the range of 5–10?mm Hg. The level of arterial oxygen saturation depends on the magnitude of the right-to-left shunt; in “pink tets,” systemic saturation may be normal, whereas in a moderately cyanotic patient at rest, it is usually 75–85%.

Selective right ventriculography best demonstrates the anatomy of the tetralogy of Fallot. Contrast medium outlines the heavily trabeculated right ventricle. The infundibular stenosis varies in length, width, contour, and distensibility (Fig. 423–4). The pulmonary valve is usually thickened, and the annulus may be small. In patients with pulmonary atresia and VSD, the anatomy of the pulmonary vessels may be extremely complex, for example, discontinuity between the right and left pulmonary arteries. Complete and accurate information regarding the anatomy of the pulmonary arteries is important when evaluating these children as surgical candidates.

Left ventriculography demonstrates the size of the left ventricle, the position of the VSD, and the overriding aorta; it also confirms mitral-aortic continuity, thereby ruling out a double-outlet right ventricle. *Aortography* or *coronary arteriography* outlines the course of the coronary arteries. In 5–10% of patients with the tetralogy of Fallot, an aberrant major coronary artery crosses over the right ventricular outflow tract; this artery must not be cut during surgical repair. Verification of normal coronary arteries is important when considering surgery in young infants who may need a patch across the pulmonary valve annulus. Echocardiography may delineate the coronary artery anatomy; angiography is reserved for cases in which questions remain.

Prognosis and Complications.

Before correction, patients with the tetralogy of Fallot are susceptible to several serious complications. Fortunately, most children undergo palliation or repair in infancy, and these complications are rare. *Cerebral thromboses*, usually occurring in the cerebral veins or dural sinuses and occasionally in the cerebral arteries, are common in the presence of extreme polycythemia and dehydration. Thromboses occur most often in patients younger than 2 yr. These patients may have iron deficiency anemia, frequently with hemoglobin and hematocrit levels in the normal range. Therapy consists of adequate

Figure 423.1-4 Lateral view of a selective right ventriculogram in a patient with the tetralogy of Fallot. The *arrow* points to an infundibular stenosis that is below the infundibular chamber (C). The narrowed pulmonary valve orifice is seen at the distal end of the infundibular chamber.

hydration and supportive measures. Phlebotomy and volume replacement with fresh frozen plasma are indicated in extremely polycythemic patients. Heparin is of little value and is contraindicated in patients with hemorrhagic cerebral infarction. Physical therapy should be instituted as early as possible.

Brain abscess is less common than cerebral vascular events and extremely rare when most patients are repaired at much younger ages. Patients with a brain abscess are usually older than 2 yr. The onset of the illness is often insidious and consists of low-grade fever or a gradual change in behavior, or both. Some patients have an acute onset of symptoms that may develop after a recent history of

headache, nausea, and vomiting. Seizures may occur; localized neurologic signs depend on the site and size of the abscess and the presence of increased intracranial pressure. CT or MRI confirms the diagnosis. Antibiotic therapy may help keep the infection localized, but surgical drainage of the abscess is usually necessary (see Chapter 595).

Bacterial endocarditis may occur in the right ventricular infundibulum or on the pulmonic, aortic, or rarely, the tricuspid valves. Endocarditis may complicate palliative shunts or, in patients with corrective surgery, any residual pulmonic stenosis or VSD. Antibiotic prophylaxis is essential before and after dental and certain surgical procedures associated with a high incidence of bacteremia (see Chapter 429).

Heart failure is not a usual feature in patients with the tetralogy of Fallot. It may occur in a young infant with “pink” or acyanotic tetralogy of Fallot. As the degree of pulmonary obstruction worsens with age, the symptoms of heart failure resolve and eventually the patient experiences cyanosis, often by 6–12 mo of age. These patients are at increased risk for hypercyanotic spells at this time.

Associated Anomalies.

An associated PDA may be present, and defects in the atrial septum are occasionally seen. A right aortic arch occurs in approximately 20% of patients with the tetralogy

of Fallot, and other anomalies of the pulmonary arteries and aortic arch may also be seen. Persistence of a left superior vena cava draining into the coronary sinus may be noted. Multiple VSDs are occasionally present and must be diagnosed before corrective surgery. Tetralogy of Fallot may also occur with an atrioventricular septal defect, often associated with Down syndrome.

Congenital absence of the pulmonary valve produces a distinct syndrome that is usually marked by signs of upper airway obstruction (see Chapter 421.1). Cyanosis may be absent, mild, or moderate; the heart is large and hyperdynamic; and a loud to-and-fro murmur is present. Marked aneurysmal dilatation of the main and branch pulmonary arteries results in compression of the bronchi and produces stridulous or wheezing respirations and recurrent pneumonia. If the airway obstruction is severe, reconstruction of the trachea at the time of corrective cardiac surgery may be required to alleviate the symptoms.

Absence of a branch pulmonary artery, most often the left, should be suspected if the roentgenographic appearance of the pulmonary vasculature differs on the two sides; absence of a pulmonary artery is often associated with hypoplasia of the affected lung. It is important to recognize the absence of a pulmonary artery because occlusion of the remaining pulmonary artery during surgery seriously compromises the already reduced pulmonary blood flow.

As one of the conotruncal malformations, the tetralogy of Fallot can be associated with the spectrum of lesions known as CATCH 22 (*c*ardiac defects, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, *h*ypocalcemia). CATCH 22 includes patients with clinical features of the *DiGeorge syndrome* (hypocalcemia, thymic hypoplasia, mild facial anomalies) or the *Shprintzen velocardiofacial syndrome* (abnormal facies, cleft palate). Cytogenetic analysis using fluorescence in situ hybridization demonstrates deletions of a segment of chromosome 22q11 known as the DiGeorge critical region.

Treatment.

Treatment of the tetralogy of Fallot depends on the severity of the right ventricular outflow tract obstruction. Infants with severe tetralogy require medical treatment and surgical intervention in the neonatal period. Therapy is aimed at providing an immediate increase in pulmonary blood flow to prevent the sequelae of severe hypoxia. The infant should be transported to a medical center adequately equipped to evaluate and treat neonates with congenital heart disease under optimal conditions. It is critical that oxygenation and normal body temperature be maintained during the transfer. Prolonged, severe hypoxia may lead to shock, respiratory failure, and intractable acidosis and will significantly reduce the chance of survival, even when surgically amenable lesions are present. Cold increases oxygen consumption, which places additional stress on a cyanotic infant, whose oxygen delivery is already limited. Blood glucose levels should be monitored because hypoglycemia is more likely to develop in infants with cyanotic heart disease.

Infants with marked right ventricular outflow tract obstruction may deteriorate rapidly because as the ductus arteriosus begins to close, pulmonary blood flow is further compromised. The intravenous administration of prostaglandin E_1 (0.05–0.20?mg/kg/min), a potent and specific relaxant of ductal smooth muscle, causes dilatation of the ductus arteriosus and usually provides adequate pulmonary blood flow until a surgical procedure can be performed. This agent should be administered intravenously as soon as cyanotic congenital heart disease is clinically suspected and continued through the preoperative period and during cardiac catheterization. Postoperatively, the infusion may be continued briefly as a pulmonary vasodilator to augment flow through a palliative shunt or through a surgical valvulotomy.

Infants with less severe right ventricular outflow tract obstruction who are stable and awaiting surgical intervention require careful observation. Prevention or prompt treatment of dehydration is important to avoid hemoconcentration and possible thrombotic episodes. Paroxysmal dyspneic attacks in infancy or early childhood may be precipitated by a relative iron deficiency; iron therapy may decrease their frequency and also improve exercise tolerance and general well-being. Red blood cell indices should be maintained in the normocytic range. Oral propranolol (0.5–1?mg/kg every 6?hr) may decrease the frequency and severity of hypercyanotic spells, but with the excellent surgery available, surgical treatment is indicated as soon as spells begin.

Infants with symptoms and severe cyanosis in the 1st mo of life have marked obstruction of the right ventricular outflow tract or pulmonary atresia. Two options are available in these infants: the first is a palliative systemic-to–pulmonary artery shunt

performed to augment pulmonary artery blood flow. The rationale for this surgery, previously the only option for these patients, is to decrease the amount of hypoxia and improve linear growth, as well as augment growth of the branch pulmonary arteries. The second option is corrective open heart surgery performed in early infancy and even in the newborn period in critically ill infants. This approach has gained more widespread acceptance as excellent short- and intermediate-term results have been reported. The advantages of corrective surgery in early infancy vs a palliative shunt and correction in later infancy are still being debated. In infants with less severe cyanosis who can be maintained with good growth and absence of hypercyanotic spells, primary repair is performed electively at between 4 and 12 mo of age.

The modified *Blalock-Taussig shunt* is currently the most common aortopulmonary shunt procedure and consists of a Gore-Tex conduit anastomosed side to side from the subclavian artery to the homolateral branch of the pulmonary artery (Fig. 423–5). Sometimes the conduit is brought directly from the ascending aorta to the main pulmonary artery and is called a *central shunt*. The Blalock-Taussig operation can be successfully performed in the newborn period with shunts 3–4?mm in diameter and has also been used successfully in premature infants.

The postoperative course of patients with a successful shunt procedure is relatively uneventful. Postoperative complications may occur after a lateral thoracotomy and include chylothorax, diaphragmatic paralysis, and Horner syndrome. **Chylothorax** may require repeated thoracocentesis and, on occasion, reoperation to ligate the thoracic duct. **Diaphragmatic paralysis** from injury to the phrenic nerve may result in a more difficult postoperative course. Prolonged ventilator support and vigorous physical therapy may be required, but diaphragmatic function usually returns in 1–2 mo unless the nerve was completely divided. Surgical plication of the diaphragm may be indicated. **Horner syndrome** is usually temporary and does not require treatment. Postoperative *cardiac failure* may be caused by a large shunt; its treatment is described in Chapter 434 . Vascular problems other than a diminished radial pulse and occasional long-term arm length discrepancy are rarely seen in the upper extremity supplied by the subclavian artery used for the anastomosis.

After a successful shunt procedure, cyanosis diminishes. The development of a continuous murmur over the lung fields after the operation indicates a functioning anastomosis. A good shunt murmur may not be heard until several days after surgery. The duration of symptomatic relief is variable. As the child grows, more pulmonary blood flow is needed and the shunt eventually becomes inadequate. When increasing cyanosis develops, a corrective operation should be performed if the anatomy is favorable. If not possible (e.g., because of hypoplastic branch pulmonary arteries) or if the 1st shunt lasts only a brief period in a small infant, a second aortopulmonary anastomosis may be required on the opposite side. Several groups have reported successful palliation of the tetralogy of Fallot in infants by balloon pulmonary valvuloplasty.

Figure 423.1-5 Physiology of a Blalock-Taussig shunt in a patient with the tetralogy of Fallot. *Circled numbers* represent oxygen saturation values. The intracardiac shunting pattern is as described for Figure 423–1 . Blood shunting left to right across the shunt from the right subclavian artery to the right pulmonary artery increases total pulmonary blood flow and results in a higher oxygen saturation than would exist without the shunt (see Fig. 423–1).

Corrective surgical therapy consists of relief of the right ventricular outflow tract obstruction by removing obstructive muscle bundles and patch closure of the VSD. If the pulmonary valve is stenotic, a valvotomy is performed. If the pulmonary valve annulus is small or the valve is extremely thickened, a valvectomy may be performed, the pulmonary valve annulus split open, and a *transannular patch* placed across the pulmonary valve ring. Any previously established systemic-to-pulmonary shunt must be obliterated before full repair. The surgical risk of total correction is less than 5%. A right ventriculotomy was the standard approach; however, a transatrial-transpulmonary approach can be used to reduce the long-term risks of a ventriculotomy. Increased bleeding in the immediate postoperative period may be a complicating factor in extremely polycythemic patients.

After successful total correction, patients are generally asymptomatic and are able to lead unrestricted lives. Immediate postoperative problems include right ventricular failure, transient heart block, residual VSD with left-to-right shunting, myocardial infarction from interruption of an aberrant coronary artery, and disproportionately increased left atrial pressure because of residual bronchial collaterals. Postoperative heart failure (particularly in patients with a transannular outflow patch) requires a positive inotropic agent such as digoxin. The long-term effects of isolated, surgically induced pulmonary valvular insufficiency are unknown, but insufficiency is generally well tolerated. The majority of patients after tetralogy repair and all of those with transannular patch repairs have a to-and-fro murmur at the left sternal border, usually indicative of mild outflow obstruction and mild to moderate pulmonary insufficiency. Patients with more marked pulmonary valve insufficiency also have moderate to marked heart enlargement. Patients with a severe residual gradient across the right ventricular outflow tract may require reoperation, but mild to moderate obstruction is virtually always present and does not require re-intervention.

Follow-up of patients 5–20 yr after surgery indicates that the marked improvement in symptoms is generally maintained. Asymptomatic patients have lower than normal exercise capacity, maximal heart rate, and cardiac output. These abnormal findings are more common in patients who underwent placement of a transannular outflow tract patch and may be less frequent when surgery is performed at an early age.

Conduction disturbances can occur after surgery. The atrioventricular node and the bundle of His and its divisions are in close proximity to the VSD and may be injured during surgery. A permanent complete heart block after surgery is rare. When present, it should be treated by placement of a permanently implanted pacemaker. Even a transient complete heart block in the immediate postoperative period is rare in tetralogy patients; it may be associated with an increased incidence of late-onset complete heart block and sudden death. Right bundle branch block is quite common on the postoperative electrocardiogram. The duration of the QRS interval has been shown to predict both the presence of residual hemodynamic derangement and the long-term risk of sudden death.

A number of children have premature ventricular beats after repair of the tetralogy of Fallot. These beats are of concern in patients with residual hemodynamic abnormalities; 24-hr electrocardiographic (Holter) monitoring studies should be

performed to be certain that occult short episodes of ventricular tachycardia are not occurring. Exercise studies may be useful in provoking cardiac arrhythmias that are not apparent at rest. In the presence of complex ventricular arrhythmias or severe residual hemodynamic abnormalities, prophylactic antiarrhythmic therapy is warranted. Re-repair is indicated if significant residual right ventricular outflow obstruction or severe pulmonary insufficiency is present.

423.2 Pulmonary Atresia with Ventricular Septal Defect

Pathophysiology.

Pulmonary atresia with VSD is an extreme form of the tetralogy of Fallot. The pulmonary valve is atretic, rudimentary, or absent, and the pulmonary trunk is atretic or hypoplastic. The entire right ventricular output is ejected into the aorta. Pulmonary blood flow is then dependent on a PDA or on bronchial collateral vessels. The ultimate prognosis depends on the degree of development of the branch pulmonary arteries, which needs to be assessed by cardiac catheterization. If these arteries are well developed, surgical repair with a homograft conduit between the right ventricle and pulmonary arteries is feasible. If the pulmonary arteries are moderately hypoplastic, the prognosis is more guarded, and extensive reconstruction may be required. Multiple *MAPCAs* may be present and can be incorporated into the repair along with the native pulmonary arteries. If the pulmonary arteries are severely hypoplastic, heart-lung transplantation may be the only therapy (see Chapter 435.2). Pulmonary atresia with VSD is also associated with the CATCH 22 deletion and either the DiGeorge or the velocardiofacial syndrome. The association of severe tracheomalacia or bronchomalacia with these severe forms of tetralogy/pulmonary atresia may complicate postoperative recovery.

Clinical Manifestations.

Patients with pulmonary atresia and VSD have findings similar to those in patients with severe tetralogy of Fallot. Cyanosis usually appears within the 1st few hours or days after birth, the prominent systolic murmur associated with the tetralogy is usually absent, the 1st heart sound is frequently followed by an ejection click caused by the enlarged aortic root, the 2nd sound is moderately loud and single, and continuous murmurs of a PDA or bronchial collateral flow may be heard over the entire precordium, both anteriorly and posteriorly. Most patients are severely cyanotic and require urgent prostaglandin

E_1 infusion and palliative surgical intervention, some patients have heart failure caused by increased pulmonary blood flow via bronchial collateral vessels (MAPCAs), and some infants have adequate pulmonary blood flow and can be managed like patients with uncomplicated tetralogy of Fallot.

Diagnosis.

The chest *roentgenogram* demonstrates a small or enlarged heart (depending on the degree of pulmonary blood flow), a concavity at the position of the pulmonary arterial segment, and often the reticular pattern of bronchial collateral flow. The *electrocardiogram* shows right ventricular hypertrophy. The *echocardiogram* identifies aortic override, a thick right ventricular wall, and atresia of the pulmonary valve. Pulsed and color Doppler echocardiographic studies show an absence of forward flow through the pulmonary valve, with pulmonary blood flow being supplied by the ductus arteriosus or by MAPCAs. At cardiac catheterization, *right ventriculography* reveals a large aorta, opacified immediately by passage of contrast medium through the VSD, but with no dye entering the lungs through the right ventricular outflow tract. The pathway of pulmonary blood flow from the aorta to the lungs (ductus or collaterals) is demonstrated. Careful delineation of both native pulmonary arteries and MAPCAs by selective contrast injection is required to determine the feasibility of surgical correction.

Treatment.

The surgical procedure of choice depends on whether the main pulmonary artery segment is adequate and on the size of the branch pulmonary arteries. In patients with small branch pulmonary arteries, surgical intervention is directed toward increasing pulmonary blood flow in the hope that pulmonary artery growth will be stimulated. Two options are currently considered: an aortopulmonary (*Blalock-Taussig* or central) shunt or the establishment of a connection from the right ventricle directly to the pulmonary artery, either by patch “unroofing” of the outflow tract or by implanting a homograft conduit. It is debated whether this type of bypass stimulates growth of the pulmonary arteries better than a standard shunt operation does.

To be a candidate for full repair, the pulmonary arteries must be of adequate size to accept the full volume of right ventricular output. Complete repair includes closure of the VSD and placement of a homograft conduit from the right ventricle to the pulmonary artery. At the time of reparative surgery, previous shunts are ligated. Because of proliferation of intimal tissue, conduit replacement is usually required in later life, and multiple replacements may be needed. Patients often have malformations of the primary divisions of the pulmonary arteries in the form of hypoplasia, multiple branch stenoses, absence of a pulmonary artery, and large bronchial collaterals. These vessels are difficult to surgically reconstruct. Some of these patients require repeated transcatheter balloon dilatation and eventual stenting of multiple branch pulmonary arterial stenoses.

Acquired total atresia of the right ventricular outflow tract may occur after an aortopulmonary shunt anastomosis for the tetralogy of Fallot. In this case, the systolic murmur resulting from pulmonary stenosis becomes attenuated and then disappears. The completeness of obstruction can be confirmed by echocardiography or by right ventriculography. Corrective surgery of the right ventricular outflow tract can be performed in a manner similar to that used for congenital pulmonary atresia.

423.3 Pulmonary Atresia with Intact Ventricular Septum

Pathophysiology.

In pulmonary atresia with an intact ventricular septum, the pulmonary valve leaflets

are completely fused to form a membrane and the right ventricular outflow tract is atretic. Because no VSD is present, no egress of blood from the right ventricle occurs. Right atrial pressure increases, and blood shunts via the foramen ovale into the left atrium, where it mixes with pulmonary venous blood and enters the left ventricle (Fig. 423–6). The combined left and right ventricular output is pumped solely by the left ventricle into the aorta. In a newborn with pulmonary atresia, the only source of pulmonary blood flow occurs via a PDA. The right ventricle is usually hypoplastic, although the degree of hypoplasia varies considerably. Patients who have a small right ventricular cavity also have a small tricuspid valve annulus, which limits right ventricular inflow. These patients may have coronary sinusoidal channels within the right ventricular wall that communicate directly with the coronary arterial circulation. The high right ventricular pressure results in desaturated blood flowing retrograde via collaterals into the coronary arteries and to the aorta. The prognosis in patients with these sinusoids is guarded. Patients with intermediate-sized or large ventricular cavities may have tricuspid insufficiency, which serves to decompress the right ventricle.

Clinical Manifestations.

As the ductus arteriosus closes in the 1st hr or days of life, infants with pulmonary atresia and an intact ventricular septum become markedly cyanotic. Untreated, most patients die within the 1st wk of life. Physical examination reveals severe cyanosis and respiratory distress. The 2nd heart sound is single and loud. Often, no murmurs are audible, but sometimes a systolic or continuous murmur can be heard secondary to ductal blood flow.

Diagnosis.

The *electrocardiogram* shows a frontal QRS axis between 0 and +90 degrees, the amount of leftward shift reflecting the degree of hypoplasia of the right ventricle. Tall, spiked P waves indicate right atrial enlargement. QRS voltages are consistent with left ventricular dominance or hypertrophy; right

Figure 423.3-6 Physiology of pulmonary atresia with an intact ventricular septum. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. A small amount of the blood entering the right atrium may cross the tricuspid valve, which is often stenotic as well. The right ventricular cavity is hypertrophied and may be hypoplastic. No outlet from the right ventricle exists because of the atretic pulmonary valve; thus, any blood entering the right ventricle returns to the right atrium via tricuspid regurgitation. Most of the desaturated blood shunts right to left via the foramen ovale into the left atrium, where it mixes with fully saturated blood returning from the lungs. The only source of pulmonary blood flow is via the patent ductus arteriosus. Aortic and pulmonary arterial oxygen saturation will be identical (definition of a total mixing lesion).

---

ventricular forces are decreased in proportion to the decreased size of the right ventricular cavity. Most patients with small right ventricles have decreased right ventricular forces, but occasionally, patients with larger, thickened right ventricular cavities may have evidence of right ventricular hypertrophy. The chest *roentgenogram* shows decreased pulmonary vascularity, the degree depending on the size of the branch pulmonary arteries and the patency of the ductus or the size of the bronchial collaterals. The heart may be variable in size. The two-dimensional *echocardiogram* is useful in estimating right ventricular dimensions and the size of the tricuspid valve annulus, which are of prognostic value. Echocardiography can often demonstrate sinusoidal channels if they are large. *Cardiac catheterization* reveals right atrial and right ventricular hypertension. Ventriculography demonstrates the size of the right ventricular cavity, the atretic right ventricular outflow tract, the degree of tricuspid regurgitation, and the presence or absence of intramyocardial sinusoids filling the coronary vessels. Aortography shows filling of the pulmonary arteries via the PDA and is helpful in determining the size and branching patterns of the pulmonary arterial bed. The aortogram is also valuable in evaluating for coronary artery stenoses because the presence of these lesions negatively affects the prognosis.

Treatment.

Infusion of prostaglandin E_1 is usually effective in keeping the ductus arteriosus open before intervention, thus reducing hypoxemia and acidemia before surgery. A surgical pulmonary valvotomy is carried out to relieve outflow obstruction whenever possible. To preserve adequate pulmonary blood flow, an aortopulmonary shunt is often performed during the same procedure. Some groups report success with surgical unroofing of the right ventricular outflow tract and patch grafting. Several centers report success with interventional catheterization, in which the imperforate pulmonary valve is first punctured with a wire or radiofrequency ablation catheter, followed by balloon valvuloplasty. The aim of surgery or interventional catheterization is to encourage growth of the right ventricular chamber by allowing some forward flow through the pulmonary valve while using the shunt to ensure adequate pulmonary blood flow. Later, if the tricuspid valve annulus and right ventricular chamber are of adequate size, a more extensive valvotomy is carried out and the shunt is taken down. If the right ventricular chamber remains hypoplastic, a modified Fontan procedure (see Chapter 423.4) allows blood to bypass the hypoplastic right ventricle by flowing to the pulmonary arteries directly from the venae cavae. When coronary artery stenoses are present and retrograde coronary perfusion occurs from the right ventricle via myocardial sinusoids, the prognosis may be grave because arrhythmias, coronary ischemia, and sudden death are common. Some of these infants benefit from heart transplantation.

423.4 Tricuspid Atresia

Pathophysiology.

In tricuspid atresia, no outlet from the right atrium to the right ventricle is present; the entire systemic venous return enters the left side of the heart by means of the foramen ovale or an associated atrial septal defect (Fig. 423–7). Left ventricular blood usually flows into the right ventricle via a VSD. Pulmonary blood flow (and thus the degree of cyanosis) depends on the size of the VSD and the presence and severity of pulmonic stenosis. Pulmonary blood flow may be augmented by or be totally dependent on a PDA. The inflow portion of the right ventricle is always missing in these patients, but the outflow portion is of variable size. If the ventricular septum is intact, the right ventricle is completely hypoplastic and pulmonary atresia is

present (see Chapter 423.3). Most patients with tricuspid atresia are recognized in the early months of life

Figure 423.4-7 Physiology of tricuspid atresia with normally related great vessels. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. The tricuspid valve is nonpatent, and the right ventricle may manifest varying degrees of hypoplasia. The only outlet from the right atrium involves shunting right to left across an atrial septal defect or patent foramen ovale to the left atrium. There, desaturated blood mixes with saturated pulmonary venous return. Blood enters the left ventricle and is ejected either through the aorta or via a ventricular septal defect (VSD) into the right ventricle. In this example, some pulmonary blood flow is derived from the right ventricle, the rest from a patent ductus arteriosus (PDA). In patients with tricuspid atresia, the PDA may close or the VSD may grow smaller and result in a marked decrease in systemic oxygen saturation.

by decreased pulmonary blood flow and cyanosis. Less often, a large VSD in the absence of right ventricular outflow obstruction can lead to high pulmonary flow; patients have mild cyanosis and heart failure. One variant of tricuspid atresia is associated with transposition of the great arteries. In this case, left ventricular blood flows directly into the pulmonary artery, whereas systemic blood must traverse the VSD and right ventricle to reach the aorta. In these patients, pulmonary blood flow is usually massively increased and heart failure develops early. If the VSD is restrictive, aortic blood flow may be compromised.

Clinical Manifestations.

Cyanosis is usually evident at birth, with the extent depending on the degree of limitation to pulmonary blood flow. An increased left ventricular impulse may be noted, in contrast to most other causes of cyanotic heart disease, in which an increased right ventricular impulse is usually present. The majority of patients have holosystolic murmurs audible along the left sternal border; the 2nd heart sound is usually single. The diagnosis is suspected in 85% of patients before 2 mo of age. In older patients, cyanosis, polycythemia, easy fatigability, exertional dyspnea, and occasional hypoxic episodes occur as a result of compromised pulmonary blood flow. Patients with tricuspid atresia are at risk for spontaneous closure of the VSD, which can occur rapidly and lead to a marked increase in cyanosis.

Diagnosis.

Roentgenographic studies show either pulmonary undercirculation (usually in patients with normally related great vessels) or overcirculation (usually in patients with transposed

great vessels). Left axis deviation and left ventricular hypertrophy are generally noted on the *electrocardiogram* (except in those with transposition of the great arteries), and these features distinguish tricuspid atresia from most other cyanotic heart lesions. The combination of cyanosis and left axis deviation is highly suggestive of tricuspid atresia. In the right precordial leads, the normally prominent R wave is replaced by an rS complex. The left precordial leads show a qR complex, followed by a normal, flat, biphasic or inverted T wave. RV_6 is normal or tall, and SV_1 is generally deep. The P waves are usually biphasic, with the initial component tall and spiked in lead II. *Two-dimensional echocardiography* reveals the presence of a fibromuscular membrane in place of a tricuspid valve, the variably small right ventricle, VSD, and the large left ventricle and aorta. The degree of obstruction at the level of the VSD or right ventricular outflow tract can be determined by direct measurement and by Doppler examination. The relationship of the great vessels (normal or transposed) can be determined. Blood flow through a patent ductus can be evaluated by color flow and pulsed Doppler examination.

Cardiac catheterization, indicated if questions remain after echocardiography, shows normal or slightly elevated right atrial pressure with a prominent “*a*” wave. If the right ventricle is entered through the VSD, the pressure may be lower than on the left because of the restrictive nature of the VSD. Right atrial angiography shows immediate opacification of the left atrium from the right atrium followed by left ventricular filling and visualization of the aorta. Absence of direct flow to the right ventricle results in an angiographic filling defect between the right atrium and the left ventricle.

Figure 423.4-8 *A*, Bidirectional Glenn shunt showing the superior vena cava–right pulmonary anastomosis. *B*, A modified Fontan procedure (cavopulmonary isolation) is completed with placement of a baffle to convey inferior vena cava blood along the lateral wall of the right atrium to the superior vena cava orifice. A 4?mm fenestration is sometimes made on the medial aspect of the polytetrafluoroethylene baffle. (From Castaneda AR, Jonas RA, Mayer JE Jr, Hanley FL: Single-ventricle tricuspid atresia. In *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

Treatment.

Management of patients with tricuspid atresia depends on the adequacy of pulmonary blood flow. Severely cyanotic neonates should be maintained on an infusion of prostaglandin E_1 until a surgical aortopulmonary shunt procedure can be performed to increase pulmonary blood flow. The Blalock-Taussig procedure (see Chapter 423.1) or a variation is the preferred anastomosis. Some patients with restrictive atrial-level communications also benefit from a Rashkind balloon atrial septostomy (see Chapter 424.2) or surgical septectomy.

Infants with increased pulmonary blood flow because of an unobstructed pulmonary outflow tract (most often patients with aortopulmonary transposition) require pulmonary arterial banding to decrease the symptoms of heart failure and protect the pulmonary bed from the development of pulmonary vascular disease. Infants with just adequate pulmonary blood flow who are well *balanced* between cyanosis and pulmonary overcirculation can be watched closely for the development of increasing cyanosis, which may occur as the VSD begins to get smaller and is an indication for surgery.

The next stage of palliation for patients with tricuspid atresia involves the creation of an anastomosis between the superior vena cava and the pulmonary arteries (*bidirectional Glenn shunt*; Fig. 423–8*A*). This procedure is performed after the patient has shown signs of outgrowing a previous aortopulmonary shunt, usually

between 4 and 12 mo of age. The benefit of the Glenn shunt is that it reduces the volume load on the left ventricle and may lessen the chance of left ventricular dysfunction developing later in life. Some centers advocate performing the Glenn anastomosis at an even earlier age (2–4 mo); the benefit of this approach has not yet been confirmed.

The modified Fontan operation is the preferred approach to later surgical management. It is often performed between 1.5 and 3 yr of age, usually after the patient is ambulatory. Initially, this procedure was performed by anastomosing the right atrium or atrial appendage directly to the pulmonary artery. A modification of the Fontan procedure known as a *cavopulmonary isolation procedure* involves anastomosing the inferior vena cava to the pulmonary arteries, either via a baffle that runs along the lateral wall of the right atrium (see Fig. 423–8*B*) or via a homograft or Gore-Tex tube running outside the heart. The advantage of this approach is that blood flows by a more direct route into the pulmonary arteries, thereby decreasing the possibility of right atrial dilatation and markedly reducing the incidence of postoperative pleural effusions, which were common with the earlier method. In this completed repair, desaturated blood flows from both venae cavae directly into the pulmonary arteries. Oxygenated blood returns to the left atrium, enters the left ventricle, and is ejected into the systemic circulation. The volume load is completely removed from the left ventricle, and the right-to-left shunt is abolished. Because of the reliance on passive filling of the pulmonary circulation, the Fontan procedure is contraindicated in patients with elevated pulmonary vascular resistance, in those with pulmonary artery hypoplasia, and in patients with left ventricular dysfunction. The patient must be in sinus rhythm and not have significant mitral insufficiency.

Postoperative problems after the Fontan procedure include marked elevation of systemic venous pressure, fluid retention, and pleural or pericardial effusions. Pleural effusions were a problem in 30–40% of patients, but the cavopulmonary isolation procedure reduces this risk to 5%. Late complications include baffle obstruction causing superior or inferior vena cava syndrome, vena cava or pulmonary artery thromboembolism, protein-losing enteropathy, and supraventricular arrhythmias (atrial flutter, paroxysmal atrial tachycardia), occasionally associated with sudden death. Left ventricular dysfunction may be a late occurrence, often in the teenage or young adult years. Heart transplantation is successful in patients with “failed” Fontan circuits.

423.5 Double-Outlet Right Ventricle with Pulmonary Stenosis

Both the aorta and pulmonary artery arising from the right ventricle characterize double-outlet right ventricle with pulmonary stenosis; the outlet from the left ventricle is a VSD into the right ventricle. The aortic and mitral valves are separated by a smooth muscular conus, similar to that seen under the normal pulmonary valve. The aorta may override the VSD by a variable amount but is at least 50% committed to the right ventricle. This defect may be viewed as part of a continuum with the tetralogy of Fallot, depending on the degree of aortic override. The physiology as well as the history, physical examination, electrocardiogram, and roentgenograms are similar to that in the tetralogy of Fallot (see Chapter 423.1). The two-dimensional *echocardiogram* demonstrates both great vessels arising from the right ventricle and mitral-aortic valve discontinuity. At *cardiac catheterization*, angiography shows that the aortic and pulmonary valves lie in the same horizontal plane and that the anteriorly displaced aorta arises predominantly or exclusively from the right ventricle. Surgical correction consists of creating an intraventricular tunnel so that the left ventricle ejects blood through the VSD, through the tunnel, and into the aorta. The pulmonary obstruction is relieved either with an outflow patch or with a pulmonary or aortic homograft conduit (*Rastelli operation*). In small infants, palliation with an aortopulmonary shunt provides symptomatic improvement and allows for adequate growth before corrective surgery is performed.

423.6 Transposition of the Great Arteries with Ventricular Septal Defect and Pulmonary Stenosis

This combination of anomalies may mimic the tetralogy of Fallot in its clinical features (see Chapter 423.1). However, because of the transposition, the site of obstruction is in the left as opposed to the right ventricle. The obstruction can be either valvular or subvalvular; the latter type may be dynamic, related to the interventricular septum or atrioventricular valve tissue, or acquired, as in patients with transposition and VSD after pulmonary arterial banding.

The age at which *clinical manifestations* initially appear varies from soon after birth to later infancy, depending on the degree of pulmonic stenosis. Clinical findings include cyanosis, decreased exercise tolerance, and poor physical development, similar to those described for the tetralogy of Fallot; however, the heart may be more enlarged. The pulmonary vasculature as seen on the *roentgenogram* is dependent on the degree of pulmonary obstruction, but it is often normal. The *electrocardiogram* usually shows right axis deviation, right and left ventricular hypertrophy, and sometimes tall, spiked P waves. *Echocardiography* confirms the diagnosis and is useful in sequential evaluation of the degree and progression of the left ventricular outflow tract obstruction. *Cardiac catheterization* shows that pulmonary arterial pressure is low and that oxygen saturation in the pulmonary artery exceeds that in the aorta. Selective right and left ventriculography demonstrates the origin of the aorta from the right ventricle, the origin of the pulmonary artery from the left ventricle, the VSD, and the site and severity of the pulmonary stenosis.

An infusion of prostaglandin E_1 should be started in neonates with cyanosis. The preferred surgical *treatment* in hypoxemic infants is an aortopulmonary shunt (see Chapter 423.1). When necessary, balloon atrial septostomy is performed to improve atrial-level mixing and to decompress the left atrium (see Chapter 424.2). The patient can then be monitored clinically until older, when a Rastelli operation is the preferred corrective procedure. The Rastelli procedure achieves physiologic and anatomic correction by (1) patch closure of the VSD, with left ventricular flow directed to the aorta, and (2) connection of the right ventricle to the pulmonary artery by ligating the proximal pulmonary artery and placing an extracardiac homograft conduit between the right ventricle and the distal pulmonary artery (Fig. 423–9). The conduit may eventually become stenotic or functionally restrictive with growth of the patient and require revision. Surgical correction by the Mustard operation (see Chapter 424.2) with simultaneous closure of the VSD and relief of left ventricular outflow obstruction may be an alternative when the position of the VSD is not suitable for a Rastelli operation. Patients with milder degrees of pulmonary stenosis amenable to simple valvotomy may be able to undergo complete correction with an

arterial switch procedure (see Chapter 424.2).

423.7 Ebstein Anomaly of the Tricuspid Valve

Pathophysiology.

Ebstein anomaly consists of downward displacement of an abnormal tricuspid valve into the right ventricle. The defect may arise from failure of the normal process by which the tricuspid valve is separated from the right ventricular myocardium (see Chapter 413). The anterior cusp of the valve retains some attachment to the valve ring, but the other leaflets are adherent to the wall of the right ventricle. The right ventricle is thus divided into two parts by the abnormal tricuspid valve: the 1st, a thin-walled *"atrialized"* portion, is continuous

Figure 423.7-9 *A*, Taussig-Bing type of double-outlet right ventricle with subpulmonary stenosis necessitating repair by the Rastelli technique. *B*, The main pulmonary artery is divided and oversewn proximally. The pulmonary valve lies within the baffle pathway. *C*, Completion of the Rastelli repair with a right ventricle–pulmonary artery allograft conduit. (From Castaneda AR, Jonas RA, Mayer JE Jr, Hanley FL: Single-ventricle tricuspid atresia. In *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

with the cavity of the right atrium; the 2nd, often smaller portion consists of normal ventricular myocardium. The right atrium is huge, and the tricuspid valve is generally regurgitant, although the degree is extremely variable. The effective output from the right side of the heart is decreased because of the poorly functioning small right ventricle, tricuspid valve regurgitation, and variable degrees of obstruction of the right ventricular outflow tract produced by the large, sail-like, anterior tricuspid valve leaflet. At times, right ventricular function is so compromised that it is unable to generate enough force to open the pulmonary valve in systole, thus producing "functional" pulmonary atresia. Some infants have true anatomic pulmonary atresia. The increased volume of right atrial blood shunts through the foramen ovale to the left atrium and produces cyanosis (Fig. 423–10).

Clinical Manifestations.

The severity of symptoms and the degree of cyanosis are highly variable and depend on the extent of displacement of the tricuspid valve and the severity of right ventricular outflow tract obstruction. In many patients, symptoms are mild and do not occur until the teenage years or young adult life; the patient may initially have fatigue or palpitations as a result of cardiac dysrhythmias. A right-to-left shunt through the foramen ovale is responsible for cyanosis and polycythemia. Central venous pressure may be normal or increased in those with tricuspid insufficiency. On palpation, the precordium is quiet. A holosystolic murmur caused by tricuspid regurgitation is audible over most of the anterior left side of the chest. A gallop rhythm is common and often associated with multiple clicks at the lower left sternal border. A scratchy diastolic murmur may also be heard at the left sternal border. This murmur is superficial and may mimic a pericardial friction rub.

Newborn infants with severe forms of Ebstein anomaly have marked cyanosis, massive cardiomegaly, and long systolic murmurs. Death may result from cardiac failure and hypoxemia. Spontaneous improvement may occur in some neonates as pulmonary vascular resistance falls normally and improves the ability of the right ventricle to provide pulmonary blood flow. The majority are dependent on a PDA for pulmonary blood flow.

Diagnosis.

The *electrocardiogram* usually shows a right bundle branch block without increased right precordial voltage, normal or tall and broad P waves, and a normal or prolonged P-R interval. Wolff-Parkinson-White syndrome (see Chapter 428) may be present; patients may have episodes of supraventricular tachycardia. On *roentgenographic examination*, heart size varies from normal to massive, box-shaped cardiomegaly caused by enlargement of the right atrium and ventricle. The pulmonary vasculature can be normal or decreased. *Echocardiography* shows the degree of displacement of the tricuspid valve leaflets, a dilated right atrium, and any right ventricular outflow tract obstruction. Pulsed and color Doppler examination demonstrates the degree of tricuspid regurgitation. In severe cases, the pulmonary valve may appear immobile and pulmonary blood flow may come solely from the ductus arteriosus. It may be difficult to distinguish true from functional pulmonary valve atresia. *Cardiac catheterization*, which is not always necessary, confirms the presence of a large right atrium, an abnormal tricuspid valve, and any right-to-left shunt at the atrial level. The risk of arrhythmia is significant during catheterization and angiographic studies.

Prognosis and Complications.

The prognosis in Ebstein anomaly is extremely variable and depends on the spectrum of severity seen. The prognosis is usually poor for neonates or infants with

Figure 423.7-10 Physiology of Ebstein anomaly of the tricuspid valve. *Circled numbers* represent oxygen saturation values. Inferior displacement of the tricuspid valve leaflets into the right ventricle has resulted in a thin-walled, low-pressure "atrialized" segment of right ventricle. The tricuspid valve is grossly insufficient *(clear arrow)*. Right atrial blood flow is shunted right to left across an atrial septal defect or patent foramen ovale into the left atrium. Some blood may cross the right ventricular outflow tract and enter the pulmonary artery; however, in severe cases, the right ventricle may generate insufficient force to open the pulmonary valve, and "functional pulmonary atresia" results. In the left atrium, desaturated blood mixes with saturated pulmonary venous return. Blood enters the left ventricle and is ejected via the aorta. In this example, some pulmonary blood flow is derived from the right ventricle, the rest from a patent ductus arteriosus (PDA). Severe cyanosis will develop in neonates with a severe Ebstein anomaly when the PDA closes.

intractable symptoms and cyanosis. Patients with milder degrees of Ebstein anomaly usually survive well into adult life.

Treatment.

Neonates with severe hypoxia who are prostaglandin dependent have been treated with an aortopulmonary shunt alone or by surgical patch closure of the tricuspid valve, atrial septectomy, and placement of an aortopulmonary shunt (*Starnes procedure*). This operation creates a functional tricuspid atresia, which can then be further repaired with first a Glenn and then a Fontan operation (see Chapter 423.4). In older children with mild or moderate disease, control of supraventricular dysrhythmias is of primary importance; surgical treatment may not be necessary until adolescence or young adulthood. In patients with severe tricuspid regurgitation, repair or replacement of the abnormal tricuspid valve along with closure of the atrial septal defect is then carried out. In some patients, a bidirectional Glenn shunt is performed, with the superior vena cava anastomosed to the pulmonary arteries. This procedure reduces the volume of blood that the dysfunctional right side of the heart has to pump, thus creating a “one-and-one-half” ventricle repair.

Chapter 424 - Cyanotic Congenital Heart Disease: Lesions Associated with Increased Pulmonary Blood Flow

424.1 d-Transposition of the Great Arteries

Transposition of the great vessels, a common cyanotic congenital anomaly, accounts for approximately 5% of all congenital heart disease. In this anomaly, the systemic veins return normally to the right atrium and the pulmonary veins return to the left atrium. The connections between the atria and ventricles are also

normal *(atrioventricular concordance)*. However, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle (Fig. 424–1). In normally related great vessels, the aorta is *posterior* and to the right of the pulmonary artery; in d-transposition of the great arteries (d-TGA), the aorta is *anterior* and to the right of the pulmonary artery (the "d" indicates a dextropositioned aorta). Desaturated blood returning from the body to the right side of the heart inappropriately goes right out the aorta and back to the body again, whereas oxygenated pulmonary venous blood returning to the left side of the heart is returned directly to the lungs. The systemic and pulmonary circulations consist of two parallel circuits. Survival in these newborns is provided by the foramen ovale and the ductus arteriosus, which permit some mixture of oxygenated and deoxygenated blood. About half of patients with TGA also have a ventricular septal defect (VSD), which provides for better mixing. The clinical findings and hemodynamics vary in relation to the presence or absence of associated defects. TGA is more common in infants of diabetic mothers and in males (3:1). TGA, especially when accompanied by other cardiac defects such as pulmonic stenosis or right aortic arch, can be associated with deletion of chromosome 22q11 (CATCH 22 [*c*ardiac defects, *a*bnormal facies, *t*hymic aplasia, *c*left palate, *h*ypoplasia], DiGeorge syndrome). Before the modern era of corrective or palliative surgery, mortality was greater than 90% in the 1st yr of life.

Figure 424.1-1 Physiology of d-transposition of the great arteries (d-TGA). *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the transposed aorta with resultant severe aortic desaturation. Fully saturated pulmonary venous blood flows into the left atrium, across the mitral valve into the left ventricle, and across the transposed pulmonary artery into the lungs. Pulmonary arterial oxygen saturation is thus increased. This lesion would not be compatible with life were it not for the ability of blood to shunt via two fetal pathways: the patent foramen ovale (PFO) and patent ductus arteriosus (PDA). Blood may shunt left to right or bidirectionally at the PFO. Because systemic vascular resistance tends to be higher than pulmonary vascular resistance, blood tends to shunt across the PDA mostly from the aorta to the pulmonary artery. As pulmonary resistance drops in the 1st few weeks of life, pulmonary blood flow will gradually increase in patients with d-TGA.

424.2 d-Transposition of the Great Arteries with Intact Ventricular Septum

d-TGA with an intact ventricular septum is also referred to as *simple TGA* or *isolated TGA*. Before birth, oxygenation of the fetus is nearly normal, but after birth, once the ductus begins to close, the minimal mixing of systemic and pulmonary blood via the patent foramen ovale is usually insufficient and severe hypoxemia ensues, generally within the 1st few days of life.

Clinical Manifestations.

Cyanosis and tachypnea are most often recognized within the 1st hours or days of life. Untreated, the vast majority of these infants would not survive the neonatal period. Hypoxemia is usually severe, but heart failure is less common. This condition is a medical emergency, and only early diagnosis and appropriate intervention can avert the development of prolonged severe hypoxemia and acidosis, which lead to death. Physical findings associated with cyanosis may be nonspecific, with the exception of cyanosis itself. The precordial impulse may be normal, or a parasternal heave may be present. The 2nd heart sound is usually single and loud, although occasionally it may be split. Murmurs may be absent, or a soft systolic ejection murmur may be noted at the midleft sternal border.

Diagnosis.

The *electrocardiogram* shows the normal neonatal right-sided dominant pattern. *Roentgenograms* of the chest may show mild cardiomegaly, a narrow mediastinum, and normal to increased pulmonary blood flow. In the early newborn period, the chest roentgenogram is generally normal. As pulmonary vascular resistance drops over the 1st wk or two of life, evidence of increased pulmonary blood flow is apparent. Arterial P_{O_2} is low and does not rise appreciably after the patient breathes 100% oxygen (*hyperoxia test*), although this finding may not be totally reliable. *Echocardiography* confirms the transposed ventricular-arterial connections. In addition, the size of the interatrial communication and the ductus arteriosus can be visualized; the degree of mixing is assessed by pulsed and color Doppler examination. The presence of left ventricular outflow tract obstruction or a VSD can also be assessed. The origins of the coronary arteries can often be imaged, although echocardiography is not as accurate as catheterization for this purpose. *Cardiac catheterization* is occasionally performed in patients for whom noninvasive imaging is diagnostically inconclusive or in patients who require emergency balloon atrial septostomy (see later). Catheterization will show right ventricular pressure to be systemic because this ventricle is supporting the systemic circulation. The blood in the left ventricle and pulmonary artery has higher oxygen saturation than that in the aorta. Depending on the age at catheterization, left ventricular and pulmonary arterial pressure can vary from systemic level to less than 50% of systemic-level pressure. *Right ventriculography* demonstrates the anterior and rightward aorta originating

from the right ventricle, as well as the intact ventricular septum. Anomalous coronary arteries are noted in 10–15% of patients. *Left ventriculography* shows that the pulmonary artery arises exclusively from the left ventricle.

Treatment.

When transposition is suspected, an *infusion of prostaglandin E_1* should be initiated immediately to maintain patency of the ductus arteriosus and improve oxygenation (dosage, 0.05–0.20?mg/kg/min). Because of the risk of apnea associated with prostaglandin infusion, an individual skilled in neonatal endotracheal intubation should be available. Hypothermia intensifies the metabolic acidosis resulting from hypoxemia, and thus the patient should be kept warm. Prompt correction of acidosis and hypoglycemia is essential.

Infants who remain severely hypoxic or acidotic despite prostaglandin infusion should undergo *Rashkind balloon atrial septostomy* (Fig. 424–2). A Rashkind atrial septostomy is usually

Figure 424.2-2 Rashkind balloon atrial septostomy. Four frames from a continuous cineangiogram show the creation of an atrial septal defect in a hypoxemic newborn infant with transposition of the great arteries and an intact ventricular septum. *A*, Balloon inflated in the left atrium. *B*, The catheter is jerked suddenly so that the balloon ruptures the foramen ovale. *C*, Balloon in the inferior vena cava. *D*, Catheter advanced to the right atrium to deflate the balloon. The time from *A* to *C* is less than 1 sec.

performed in all patients in whom any significant delay in surgery is necessary. At most centers, the arterial switch (Jantene) operation is performed within the 1st 2 wk of life. If the arterial switch is planned immediately, catheterization and atrial septostomy may often be avoided.

A successful Rashkind atrial septostomy should result in a rise in Pa_{O_2} to 35–50?mm Hg and elimination of any pressure gradient across the atrial septum. Some patients with TGA and VSD may require balloon atrial septostomy because of poor mixing, even though the VSD is large. Others may benefit from decompression of the left atrium to alleviate the symptoms of increased pulmonary blood flow and left-sided heart failure.

The *arterial switch (Jantene) procedure* is the surgical treatment of choice for neonates with d-TGA and an intact ventricular septum and is usually performed within the 1st 2 wk of life. The reason for this urgency is that as pulmonary vascular resistance declines after birth, pressure in the left ventricle (connected to the pulmonary vascular bed) also declines. This drop in pressure results in a decrease in left ventricular mass over the 1st few weeks of life. If the arterial switch operation is attempted after left ventricular pressure has declined too far, the left ventricle will be unable to generate adequate pressure to pump blood to the systemic circulation. The operation involves dividing the aorta and pulmonary artery just above the sinuses and re-anastomosing them in their correct anatomic positions. The coronary arteries are then removed from the old aortic root along with a button of aortic wall and re-implanted in the old pulmonary root (the “neoaorta”). By using a button of great vessel tissue, the surgeon avoids having to suture directly onto the coronary artery (Fig. 424–3). Rarely, a two-stage arterial switch procedure, with initial placement of a pulmonary artery band, may be used in patients older than 3–4 wk who already have a reduction in left ventricular muscle mass and pressure.

The arterial switch procedure has a survival rate of 90–95% for uncomplicated d-TGA. It restores the normal physiologic relationships of systemic and pulmonary arterial blood flow and eliminates the long-term complications of the atrial switch procedure (see the next paragraph).

Previous operations for d-TGA consisted of some form of *atrial switch procedure* (Mustard or Senning operation). In older infants, these procedures produced excellent early survival (about 85–90%), but significant long-term morbidity. Atrial switch procedures reverse blood flow patterns at the atrial level by the surgical creation of an intra-atrial baffle that allows systemic venous blood to be directed to the left atrium and the left ventricle and then, via the pulmonary artery, into the lungs. The same baffle also permits oxygenated pulmonary venous blood to cross over to the right atrium, right ventricle, and aorta. Atrial switch procedures involve significant atrial surgery and may result in the late development of atrial conduction disturbances, sick sinus syndrome with bradyarrhythmia and tachyarrhythmia, atrial flutter, sudden death, superior or inferior vena cava syndrome, edema, ascites, and protein-losing enteropathy. Atrial switch operations are reserved for patients who are not candidates for the arterial switch procedure (TGA and severe pulmonic stenosis).

424.3 Transposition of the Great Arteries with Ventricular Septal Defect

If the VSD associated with TGA is small, the clinical manifestations, laboratory findings, and treatment are similar to those described previously for transposition with an intact ventricular septum. A harsh systolic murmur is audible at the lower left sternal border and results from flow through the defect. Many of these small defects eventually close spontaneously and are often not addressed at the time of surgery.

When the VSD is large and not restrictive to ventricular ejection, significant mixing of oxygenated and deoxygenated blood usually occurs and *clinical manifestations* of cardiac failure are seen. The onset of cyanosis may be subtle and frequently delayed, and its intensity is variable. Cyanosis can generally be recognized within the 1st mo of life, but it may remain undiagnosed in some infants for several months. The murmur is holosystolic and generally indistinguishable from that produced by a large VSD in patients with normally related great arteries. The heart is usually significantly enlarged.

Cardiomegaly, a narrow mediastinal waist, and increased pulmonary vascularity are demonstrated on the *chest roentgenogram*. The *electrocardiogram* shows prominent P waves and isolated right ventricular hypertrophy or biventricular hypertrophy. Occasionally, dominance of the left ventricle is present. Usually, the QRS axis is to the right, but it is sometimes normal or even to the left. The diagnosis can be confirmed by *echocardiography*, and the extent of pulmonary blood flow can also be assessed by the degree of enlargement of the left atrium and ventricle. In equivocal

cases, the diagnosis can be confirmed by *cardiac catheterization*. Right and left ventriculography can indicate the presence of arterial transposition and demonstrate the site and size of the VSD. Peak systolic pressure is equal in the two ventricles, the aorta, and the pulmonary artery. Left atrial pressure may be much higher than right atrial pressure, a finding indicative of a restrictive communication at the atrial level. At the time of cardiac catheterization, Rashkind balloon atrial septostomy may be performed to decompress the left atrium, even when adequate mixing is occurring at the ventricular level.

Surgical treatment is advised soon after diagnosis, usually within the 1st months of life, because heart failure and failure to thrive are difficult to manage and pulmonary vascular disease can develop unusually rapidly. Management includes digitalis and diuretics to lessen the symptoms of heart failure while awaiting surgical repair.

Patients with TGA and a VSD without pulmonic stenosis can be managed with an arterial switch procedure combined with

Figure 424.3-3 Method for translocating the coronary arteries in the arterial switch (Jantene) procedure. *A*, The aorta (anterior) and the pulmonary artery (posterior) have been transected to allow visualization of the left and right coronary arteries. The coronaries have been excised from their respective sinuses, including a large flap (button) of arterial wall. Equivalent segments of the wall of the pulmonary artery (which will become the neoaorta) are also removed. *B*, The aortocoronary buttons are sutured into the proximal portion of the neoaorta. With this technique all sutures are placed in the button of aortic wall rather than directly on the coronary arteries. *C*, Completed anastomosis of the left and right coronary arteries to the neoaorta. (Adapted from Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant. Philadelphia*, WB Saunders, 1994.)

VSD closure. The arterial switch operation can be safely performed after the 1st 2 wk of life because the VSD results in equal pressure in both ventricles and prevents regression of left ventricular muscle mass.

Without treatment, the *prognosis* is poor; most patients succumb in the 1st yr of life because of heart failure, hypoxemia, and pulmonary hypertension. In the past, some survived infancy with medical therapy alone, but pulmonary vascular disease often developed. The clinical picture and treatment of these patients are similar to those described with Eisenmenger syndrome secondary to an isolated large VSD (see Chapter 426.2).

424.4 l-Transposition of the Great Arteries (Corrected Transposition)

In l-transposition, the atrioventricular relationships are discordant, with the right atrium connected to the left ventricle and the left atrium to the right ventricle *(ventricular inversion)*. The great arteries are also transposed, with the aorta arising from the right ventricle and the pulmonary artery from the left. The aorta arises to the left of the pulmonary artery (hence the designation “l” for levotransposition). The aorta may be anterior to the pulmonary artery; usually, they are nearly side by side.

Desaturated systemic venous blood is returned to a normally positioned right atrium, from which it passes through a bicuspid atrioventricular (mitral) valve into a right-sided ventricle that has the architecture and smooth wall morphologic features of the normal left ventricle (Fig. 424–4). Because transposition is also present, desaturated blood ejected from this left ventricle enters the transposed pulmonary artery and flows into the lungs. Oxygenated pulmonary venous blood returns to a normally positioned left atrium, passes through a tricuspid atrioventricular valve into a left-sided ventricle, which has the trabeculated morphologic features of a normal right ventricle, and is then ejected into the transposed aorta. The double inversion of the atrioventricular and ventriculoarterial relationships results in desaturated right atrial blood reaching the lungs and oxygenated pulmonary venous blood appropriately flowing to the aorta. The circulation is physiologically “corrected.” Without other defects, the hemodynamics would be nearly normal. However, in most patients, associated anomalies coexist: VSD, Ebstein-like abnormalities of the left-sided atrioventricular (tricuspid) valve, pulmonary valvular or subvalvular stenosis (or both), and atrioventricular conduction disturbances (complete heart block).

Clinical Manifestations.

Symptoms and signs are widely variable and are determined by the associated lesions. If pulmonary outflow is unobstructed, the clinical signs are similar to those of an isolated VSD. If the TGA is associated with pulmonary stenosis and a VSD, the clinical signs are similar to those of tetralogy of Fallot.

Diagnosis.

The *chest roentgenogram* may suggest the abnormal position of the great arteries; the ascending aorta occupies the upper left border of the cardiac silhouette and has a straight profile. In addition to atrioventricular conduction disturbances, the *electrocardiogram* may show abnormal P waves; absent Q waves in V_6 ; abnormally present Q waves in leads III, aVR, aVF, and V_1 ; and upright T waves across the precordium.

Surgical treatment of the associated anomalies, most often the VSD, is complicated by the position of the bundle of His, which can be injured at the time of surgery and result in heart block. Identification of the usual course of the bundle in corrected transposition (running superior to the defect) has been

Figure 424.4-4 Physiology of l- or corrected transposition of the great arteries (l-TGA) with a ventricular septal defect and pulmonic stenosis (VSD + PS). *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Blood from the right atrium flows through the mitral valve into the “inverted” left ventricle. However, the left ventricle is attached to the transposed pulmonary artery. Therefore, despite the anomalies, desaturated blood still winds up in the pulmonary circulation. Saturated blood returns to the left atrium, traverses the tricuspid valve into the “inverted” right ventricle, and is pumped into the transposed aorta. This circulation would be totally “corrected” were it not for the frequent association of other congenital anomalies, in this case, VSD + PS. Because of the stenotic pulmonary valve, some left ventricular blood flow crosses the VSD and into the right ventricle and the ascending aorta,

and systemic desaturation results.

accomplished by mapping of the conduction system so that the surgeon can avoid the bundle of His during open heart repair.

424.5 Double-Outlet Right Ventricle Without Pulmonary Stenosis

In double-outlet right ventricle without pulmonary stenosis, both the aorta and the pulmonary artery arise from the right ventricle. The only outlet from the left ventricle is through a VSD. The *clinical manifestations* closely simulate those of an uncomplicated VSD with a large left-to-right shunt, although mild systemic desaturation may be present because of mixing of oxygenated and deoxygenated blood in the right ventricle. The *electrocardiogram* usually shows biventricular hypertrophy. *Echocardiography* is diagnostic and shows the right ventricular origin of both great vessels and their anteroposterior relationship, as well as the position of the VSD. *Cardiac catheterization* demonstrates the proximity of the VSD to the aorta, which results in most of the left ventricular blood being ejected directly into the systemic circulation. The angiogram also confirms the lack of mitral-aortic fibrous continuity and shows the aortic valve displaced superiorly and at the same level as the pulmonary valve. It is important to differentiate this condition from a simple VSD.

Surgical correction is accomplished by creation of an intracardiac tunnel. Blood is then ejected from the left ventricle via the VSD into the aorta. Pulmonary arterial banding may be required in infancy, followed by surgical correction when the child is bigger. When associated pulmonary stenosis is present, the cyanosis is more marked and pulmonary blood flow is decreased (see Chapter 423).

424.6 Double-Outlet Right Ventricle with Transposition of the Great Arteries (Taussig-Bing Anomaly)

In double-outlet right ventricle with TGA, the VSD is located above the crista supraventricularis (subarterial VSD) and is either directly subpulmonary or related to both the pulmonary and aortic valves (doubly committed VSD). Patients experience cardiac failure early in infancy and are at risk for the development of pulmonary vascular disease and cyanosis. Cardiomegaly is usual, and a parasternal systolic ejection murmur is audible, sometimes preceded by an ejection click and loud closure of the pulmonary valve. Left-sided obstructive lesions are frequent, including coarctation of the aorta, interruption of the aortic arch, and a restrictive VSD, which obstructs left ventricular ejection. The *electrocardiogram* shows right axis deviation and right, left, or biventricular hypertrophy. The *roentgenogram* documents cardiomegaly, a large left atrium, and prominence of the pulmonary artery and pulmonary vasculature. The anatomic features of the anomaly and associated abnormalities are best demonstrated by a combination of echocardiography and selective right and left ventriculography. Palliation may be achieved by pulmonary arterial banding in infancy and surgical correction at a later age, which may be accomplished by a Rastelli procedure (see Chapter 423) or by an arterial switch procedure (see Chapter 424.2).

424.7 Total Anomalous Pulmonary Venous Return

Pathophysiology.

Abnormal development of the pulmonary veins may result in either partial or complete anomalous drainage into the systemic venous circulation. Partial anomalous pulmonary venous return is usually an acyanotic lesion (see Chapter 419.4). Total anomalous pulmonary venous return (TAPVR) allows total mixing of systemic venous and pulmonary venous blood flow within the heart and thus produces cyanosis.

In TAPVR, the heart has no direct pulmonary venous connection into the left atrium. The pulmonary veins may drain *above the diaphragm* into the right atrium directly, into the coronary sinus, or into the superior vena cava via a “vertical vein,” or they may drain *below the diaphragm* and join into a “descending vein” that enters into the inferior vena cava or one of its major tributaries, often via the ductus venosus. This latter form of anomalous venous drainage is most commonly associated with obstruction, usually as the ductus venosus closes soon after birth, although supracardiac anomalous veins may also become obstructed. Occasionally, the drainage may be mixed, with some veins draining above and others below the diaphragm.

All forms of TAPVR involve mixing of oxygenated and deoxygenated blood before or at the level of the right atrium. Right atrial blood either passes into the right ventricle and pulmonary artery or passes through an atrial septal defect (ASD) or patent foramen ovale into the left atrium. The right atrium and ventricle and the pulmonary artery are generally enlarged, whereas the left atrium and ventricle may be normal or small. The manifestations of TAPVR depend on the presence or absence of obstruction of the venous channels (Table 424–1). If pulmonary venous return is obstructed, severe pulmonary congestion and pulmonary hypertension develop; rapid deterioration occurs

TABLE 424.7-1 -- Anomalous Pulmonary Venous Return

% and Site of Connection	% with Severe Obstruction
Supracardiac (50)	
Left superior vena cava (40)	40
Right superior vena cava (10)	75
Cardiac (25)	
Coronary sinus (20)	10

Right atrium (5)	5
Infracardiac (20)	95–100
Mixed (5)	

without surgical intervention. Obstructed TAPVR is a pediatric cardiac surgical emergency because prostaglandin therapy may not be helpful.

Clinical Manifestations.

Three major clinical patterns of TAPVR are seen. Some are manifested in the neonatal period as severe obstruction to pulmonary venous return, most prevalent in the infracardiac group (see Table 424–1). Cyanosis and severe tachypnea are prominent, but murmurs may not be present. Infants are severely ill and fail to respond to mechanical ventilation. Rapid diagnosis and surgical correction are necessary for survival. Another group is characterized by heart failure in early life, but these infants have only mild or moderate obstruction to pulmonary venous return and a large left-to-right shunt. Because pulmonary artery hypertension is present, these infants are severely ill. Systolic murmurs are audible along the left sternal border, and a gallop rhythm may be present. A continuous murmur is occasionally heard along the upper left sternal border over the pulmonary area. Cyanosis is mild. The third group of patients with TAPVR consists of those in whom pulmonary venous obstruction is not present; these patients have total mixing of systemic venous and pulmonary venous blood and a large left-to-right shunt. Pulmonary hypertension is absent, and these patients are less likely to be severely symptomatic during infancy. Clinical cyanosis is usually mild or absent.

Diagnosis.

The *electrocardiogram* demonstrates right ventricular hypertrophy (usually a qR pattern in V_3 R and V_1 , and the P waves are frequently tall and spiked). *Roentgenograms* are

Figure 424.7-5 Roentgenograms of total anomalous pulmonary venous return to the left superior vena cava. *A*, Preoperative image. *Arrows* point to the supracardiac shadow, which produces the snowman or figure 8 configuration. Cardiomegaly and increased pulmonary vascularity are evident. *B*, Postoperative image showing a decrease in the size of the heart and the supracardiac shadow.

pathognomonic in older children if the anomalous pulmonary veins enter the innominate vein and persistent left superior vena cava (Fig. 424–5). A large supracardiac shadow can be seen, which together with the normal cardiac shadow forms a “snowman” appearance. This appearance is not helpful for diagnosis in early infancy because of the thymus. In most cases without obstruction, the heart is enlarged, the pulmonary artery and right ventricle are prominent, and pulmonary vascularity is increased. In neonates with marked pulmonary venous obstruction, the chest roentgenogram demonstrates a perihilar pattern of pulmonary edema and a small heart. This appearance can be confused with primary pulmonary disease. The differential diagnosis includes persistent pulmonary hypertension of the newborn, respiratory distress syndrome, pneumonia (bacterial, meconium aspiration), pulmonary lymphangiectasia, and other heart defects (hypoplastic left heart syndrome).

The *echocardiogram* demonstrates a large right ventricle and usually identifies the pattern of abnormal pulmonary venous connections. The demonstration of a vessel in the abdomen with Doppler venous flow away from the heart is pathognomonic of TAPVR below the diaphragm. Shunting occurs almost exclusively from right to left at the atrial level.

Cardiac catheterization shows that the oxygen saturation of blood in both atria, both ventricles, and the aorta is more or less similar, indicative of a *total mixing lesion*. An increase in systemic venous saturation occurs at the site of entry of the abnormal pulmonary venous channel. In older patients, pulmonary arterial and right ventricular pressure may be only moderately elevated, but in infants with pulmonary venous obstruction, pulmonary hypertension is usual. *Selective pulmonary arteriography* shows the anatomy of the pulmonary veins and their point of entry into the systemic venous circulation. MRI and CT may be alternative methods of confirming the diagnosis.

Treatment.

Surgical correction of TAPVR is indicated during infancy. Before surgery, infants may be stabilized with prostaglandin E_1 to dilate the ductus venosus and the ductus arteriosus. Some may require balloon atrial septostomy, but it is of little or no benefit in the presence of pulmonary venous obstruction. Surgically, the common pulmonary venous trunk is anastomosed directly to the left atrium, the ASD is closed, and the

connection to the systemic venous circuit is interrupted. Results have been generally good, even for critically ill neonates. If postoperative hemodynamics are normal, the prognosis is excellent. The postoperative period may be complicated by pulmonary vascular hypertensive crises. In some patients, especially those in whom the diagnosis was delayed, persistent pulmonary hypertension may occur, and the long-term prognosis in these patients is poor. Inhaled nitric oxide or extracorporeal membrane oxygenation may be necessary. Long-term complications include re-stenosis of the pulmonary venous channel–to–left atrial communication. In patients with stenosis or hypoplasia of the individual pulmonary veins, the prognosis is poor.

424.8 Truncus Arteriosus

Pathophysiology.

In truncus arteriosus, a single arterial trunk (truncus arteriosus) arises from the heart and supplies the systemic, pulmonary, and coronary circulations. A VSD is always present, with the truncus overriding the defect and receiving blood from both the right and left ventricles (Fig. 424–6). The number of truncal valve cusps varies from two to as many as six. The pulmonary arteries may arise together from the posterior left side of the persistent truncus arteriosus and then divide into left and right pulmonary

arteries (type I truncus arteriosus). In types II and III truncus arteriosus, no main pulmonary artery is present, and the right and left pulmonary arteries arise from separate orifices in the posterior (type II) or lateral (type III) aspects of the truncus arteriosus. Type IV truncus has no identifiable connection between the heart and pulmonary arteries, and pulmonary blood flow is derived from *major aortopulmonary*

Figure 424.8-6 Physiology of truncus arteriosus. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the truncus. Saturated blood returning from the left atrium enters the left ventricle and is also ejected into the truncus. The common aortopulmonary trunk gives rise to the ascending aorta and to the main or branch pulmonary arteries. Oxygen saturation in the aorta and pulmonary arteries is usually the same (definition of a total mixing lesion). As pulmonary vascular resistance decreases over the 1st few weeks of life, pulmonary blood flow increases dramatically and mild cyanosis and congestive heart failure result.

collateral arteries arising from the transverse or descending aorta; this form has also been called *pseudotruncus* but is essentially a form of pulmonary atresia with a VSD (see Chapter 423.2).

Both ventricles are at systemic pressure and both eject blood into the truncus. When pulmonary vascular resistance is relatively high immediately after birth, pulmonary blood flow may be normal; as pulmonary resistance drops over the 1st mo of life, blood flow to the lungs is greatly increased and heart failure ensues. Truncus arteriosus is a *total mixing lesion* with total admixture of pulmonary and systemic venous return. Because of the large volume of pulmonary blood flow, clinical cyanosis is usually minimal. If the lesion is left untreated, pulmonary resistance eventually increases, pulmonary blood flow decreases, and cyanosis becomes more apparent (Eisenmenger physiology; see Chapter 426.2). The truncal valve is occasionally incompetent, which significantly complicates medical and surgical management.

Clinical Manifestations.

The clinical signs of truncus arteriosus vary with age and depend on the level of pulmonary vascular resistance. In the immediate newborn period, signs of heart failure are usually absent; a murmur and minimal cyanosis are the initial signs. In most older infants, pulmonary blood flow is torrential and the clinical picture is dominated by heart failure. Cyanosis is minimal. Runoff of blood from the truncus to the pulmonary circulation may result in a wide pulse pressure and bounding pulses. These findings may be further exaggerated if truncal valve insufficiency is present. The heart is usually enlarged, and the precordium is hyperdynamic. The 2nd heart sound is loud and single. A systolic ejection murmur, sometimes accompanied by a thrill, is generally audible along the left sternal border. The murmur is frequently preceded by an early systolic ejection click. In the presence of truncal valve insufficiency, a high-pitched early diastolic decrescendo murmur is heard at the midleft sternal border. An apical mid-diastolic rumbling murmur caused by increased flow through the mitral valve is audible with the bell of the stethoscope. In older children with restricted pulmonary blood flow secondary to pulmonary vascular obstructive disease, progressive cyanosis, polycythemia, and clubbing develop. Truncus arteriosus may be associated with DiGeorge syndrome (Chapter 115.1).

Diagnosis.

The *electrocardiogram* shows right, left, or combined ventricular hypertrophy. The *chest roentgenogram* also shows considerable variation. The cardiac enlargement is due to prominence of both ventricles. The truncus may produce a prominent shadow that follows the normal course of the ascending aorta and aortic knob; the aortic arch is to the right in 50% of patients. Sometimes a high bulge left of the aortic knob is produced by the main or left pulmonary artery. Pulmonary vascularity is increased after the 1st few weeks of life. *Echocardiography* demonstrates the large truncal artery overriding the VSD and the pattern of origin of the branch pulmonary arteries. Associated anomalies such as an interrupted aortic arch may be noted. Pulsed and color Doppler studies are used to evaluate truncal valve regurgitation. If required, *cardiac catheterization* shows a left-to-right shunt at the ventricular level, with right-to-left shunting into the truncus. Systolic pressure in both ventricles and the truncus is similar. Angiography reveals the large truncus arteriosus and more precisely defines the origin of the pulmonary arteries.

Prognosis and Complications.

Without surgery, many of these patients succumb during infancy or by the 1st or 2nd yr of life. If pulmonary blood flow is restricted by the development of pulmonary vascular disease, the patient may survive into early adulthood. Starting in the late 1970s, surgical results have been very good, and many patients with repaired truncus are entering young adulthood. As a conotruncal lesion, truncus arteriosus is often associated with a deletion of chromosome 22q11 (CATCH

22, DiGeorge syndrome) and associated endocrine, immunologic, facial, and pulmonary abnormalities.

Treatment.

In the 1st few weeks of life, many of these infants can be managed with anticongestive medications; however, as pulmonary vascular resistance falls, heart failure symptoms worsen and surgery is indicated, usually in the 1st few weeks of life. Delay of surgery much beyond 4–8 wk may increase the likelihood of pulmonary vascular disease; some centers advocate neonatal repair at the time of diagnosis. At surgery, the VSD is closed, the pulmonary arteries are separated from the truncus, and continuity is established between the right ventricle and the pulmonary arteries with a homograft conduit (Rastelli repair). Immediate surgical results are excellent, but after repair the conduit must be replaced, often several times, as the child grows. In older patients who already have pulmonary vascular obstruction, routine surgical treatment is contraindicated and heart-lung transplantation is the only option.

424.9 Single Ventricle (Double-Inlet Ventricle, Univentricular Heart)

Pathophysiology.

With a single ventricle, both atria empty through a common atrioventricular valve or via two separate valves into a single ventricular chamber, with *total mixing* of systemic and pulmonary venous return. This chamber may have left, right, or indeterminate ventricular anatomic characteristics. The aorta and pulmonary artery both arise from this single chamber, although one of the great vessels may originate from a rudimentary outflow chamber. The aorta may be posterior, anterior *(malposition)*, or side by side with the pulmonary artery and either to the right or to the left. Pulmonary stenosis or atresia is common.

Clinical Manifestations.

The clinical picture is variable and depends on the associated intracardiac anomalies. If pulmonary outflow is obstructed, the findings may be similar to those of tetralogy of Fallot: marked cyanosis without heart failure. If pulmonary outflow is unobstructed, the findings are similar to those of transposition with VSD: minimal cyanosis with marked heart failure.

In patients with pulmonary stenosis, cyanosis is present in infancy and increases in intensity during childhood, when clubbing and polycythemia appear. Dyspnea and fatigue are frequent, cardiomegaly is mild or moderate, a left parasternal lift is palpable, and a systolic thrill is common. The systolic ejection murmur is usually loud; an ejection click may be audible, and the 2nd heart sound is single and loud.

Patients with unobstructed pulmonary outflow have torrential pulmonary blood flow and are initially seen in early infancy with tachypnea, dyspnea, failure to thrive, and recurrent pulmonary infections. Cyanosis is only mild or moderate. Cardiomegaly is generally marked, and a left parasternal lift is palpable. The systolic ejection murmur is not usually intense, and the 2nd heart sound is loud and closely split. A 3rd heart sound is common and may be followed by a short mid-diastolic rumbling murmur caused by increased flow through the atrioventricular valves. The eventual development of pulmonary vascular disease reduces pulmonary blood flow so that the cyanosis increases and signs of cardiac failure appear to improve (Eisenmenger physiology; see Chapter 426.2).

Diagnosis.

Findings on the *electrocardiogram* are nonspecific. P waves are normal, spiked, or bifid. The precordial lead pattern suggests right ventricular hypertrophy, combined ventricular hypertrophy, or sometimes left ventricular dominance. The initial QRS forces are usually to the left and anterior. *Roentgenographic examination* confirms the degree of cardiomegaly. If present, a rudimentary outflow chamber may produce a bulge on the upper left border of the cardiac silhouette in the posteroanterior projection. In the absence of pulmonary stenosis, pulmonary vasculature is increased, whereas in the presence of pulmonary stenosis, pulmonary vasculature is diminished. Absence or near absence of the ventricular septum is the principal *echocardiographic* sign. The echocardiogram can usually determine whether the single ventricle has right, left, or mixed morphologic features. The presence of a rudimentary outflow chamber under one of the great vessels can be identified, and pulsed Doppler can be used to determine whether flow through this communication *(bulboventricular foramen)* is obstructed.

If *cardiac catheterization* is performed, arterial oxygen saturation is seen to be decreased in the presence of severe pulmonary stenosis or obstructive pulmonary hypertension, but it may be near normal when pulmonary blood flow is unimpeded. The pressure in the ventricular chamber is at systemic level; a gradient may be demonstrated across the entrance to a rudimentary outflow chamber. Pressure measurements and angiography demonstrate whether pulmonary stenosis is present. Severe pulmonary hypertension may be demonstrated in older patients in the absence of pulmonary stenosis.

Prognosis and Complications.

Unoperated, some patients succumb during infancy from heart failure. Others may survive to adolescence and early adult life but finally succumb to the effects of chronic hypoxemia or, in the absence of pulmonary stenosis, to the effects of pulmonary vascular disease. Patients with moderate pulmonary stenosis have the best prognosis because pulmonary blood flow, though restricted, is still adequate.

Treatment.

If pulmonary stenosis is severe, an aortopulmonary shunt is indicated. If pulmonary blood flow is unrestricted, pulmonary arterial banding is used to control heart failure and prevent progressive pulmonary vascular disease. The *Glenn shunt* followed by a modified *Fontan* operation (cavopulmonary isolation procedure, see Chapter 423.4) is the ultimate treatment of choice. If subaortic stenosis is present because of a restrictive connection to a rudimentary outflow chamber, surgical relief can be provided by anastomosing the proximal pulmonary artery to the side of the ascending aorta *(Damus-Stansyl-Kaye operation)*.

424.10 Hypoplastic Left Heart Syndrome

Pathophysiology.

The term *hypoplastic left heart* is used to describe a related group of anomalies that include underdevelopment of the left side of the heart (e.g., atresia of the aortic or mitral orifice) and hypoplasia of the ascending aorta. The left ventricle may be small and nonfunctional or totally atretic; the right ventricle maintains both the pulmonary and systemic circulation (Fig. 424–7). Pulmonary venous blood passes through an atrial defect or dilated foramen ovale from the left to the right side of the heart, where it mixes with systemic venous blood *(total mixing lesion)*. When the ventricular septum is intact, which is usually the case, all the right ventricular blood is ejected into the main pulmonary artery; the descending aorta is supplied via the ductus arteriosus, with flow from the ductus also filling the ascending aorta and coronary arteries in a retrograde fashion. In the presence of a VSD and a patent but small aortic orifice, right ventricular blood is ejected into the small left ventricle and ascending aorta, as well as the pulmonary artery. The major hemodynamic abnormalities are inadequate maintenance of the systemic circulation and, depending on the size of the atrial-level communication, either pulmonary venous hypertension (restrictive foramen ovale) or pulmonary overcirculation (moderate or

large ASD).

Figure 424.10-7 Physiology of hypoplastic left heart syndrome (HLHS). *Circled numbers* represent oxygen saturation values. HLHS is not a single lesion but a constellation of different degrees of hypoplasia of the left-sided heart structures. This drawing shows a patent mitral valve, a small left ventricular cavity, and a diminutive ascending aorta. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the pulmonary artery. Because of the markedly decreased left ventricular compliance, most of the pulmonary venous blood returning to the left atrium shunts left to right at the atrial level. A small amount of left atrial blood will cross the mitral valve and be ejected into the tiny ascending aorta. The right ventricular oxygen saturation represents a mixing of desaturated systemic venous blood and saturated pulmonary venous blood. Pulmonary artery blood flows into the pulmonary arteries as well as right to left across the patent ductus arteriosus (PDA) into the aorta. Ductal blood flows prograde to the descending aorta as well as retrograde to the ascending aorta, where it supplies the head and neck vessels in addition to the coronary arteries (which arise off the small ascending aorta). Closure of the PDA results in profound hypoxia and circulatory collapse.

Clinical Manifestations.

Although cyanosis may not always be obvious in the 1st 48?hr of life, a grayish blue color of the skin is soon apparent and denotes a mix of cyanosis and hypoperfusion. The condition is diagnosed in most infants in the 1st few hours or days of life. If the ductus arteriosus partially closes, signs of systemic hypoperfusion and shock predominate. Signs of heart failure usually appear within the 1st few days or weeks of life and include dyspnea, hepatomegaly, and low cardiac output. The peripheral pulses may be weak or absent. Cardiac enlargement is usual, with a palpable right ventricular parasternal lift. A nondescript systolic murmur is generally audible. Extracardiac anomalies, particularly of the kidneys and central nervous system, may be present.

Diagnosis.

On the *chest roentgenogram*, the heart is variable in size in the 1st days of life, but cardiomegaly develops rapidly and is associated with increased pulmonary vascularity. The initial *electrocardiogram* may show only the normal right ventricular dominance with poor ventricular voltage, but later, P waves become prominent and right ventricular hypertrophy is usual. The *echocardiogram* is diagnostic and demonstrates absence or hypoplasia of the mitral valve and aortic root, a variably small left atrium and left ventricle, and a large right atrium and right ventricle. The size of the atrial communication by which pulmonary venous blood leaves the left atrium can be assessed directly and by pulsed and color flow Doppler studies. Suprasternal notch views identify the small ascending aorta and transverse aortic arch and may also show a discrete coarctation of the aorta in the juxtaductal area. Doppler echocardiography demonstrates the absence of anterograde flow in the ascending aorta and retrograde flow via the ductus arteriosus. These findings are so characteristic that the diagnosis of hypoplastic left heart syndrome can usually be made without any need for *cardiac catheterization*. If catheterization is necessary, the hypoplastic ascending aorta can be demonstrated by angiography.

Prognosis and Complications.

Patients most often succumb during the 1st months of life, usually during the 1st wk or two. Occasionally, unoperated patients may live for months or rarely years. One third of infants with hypoplastic left heart syndrome have evidence of either a major or minor central nervous system abnormality. Other dysmorphic features may be found in up to 40% of patients. Thus, careful preoperative evaluation (genetic, neurologic, and ophthalmologic) should be performed in patients being considered for either standard surgical therapy or cardiac transplantation.

Treatment.

Surgical therapy for hypoplastic left heart syndrome has been associated with survival rates of 80–90% for the first-stage Norwood operation in many centers. Management options include palliation (the Norwood procedure; Fig. 424–8), heart transplantation, and in very few patients, supportive expectant care. Considerable controversy has arisen regarding which of the two surgical options is optimal, as well as concern over whether a “do nothing” option should be offered to parents given the good surgical results.

If a **Norwood procedure** is to be performed, preoperative medical management includes correction of acidosis and hypoglycemia, maintenance of ductus arteriosus patency with prostaglandin E_1 to support systemic blood flow, and prevention of hypothermia. Preoperative management should avoid excessive pulmonary blood flow; often, patients are managed on room air or with a F_{IO_2} of 18% with nitrogen gas blended into the oxygen source. Balloon dilatation of the atrial septum may be indicated if surgery is delayed.

The Norwood procedure is usually performed in three stages. The first stage (see Fig. 424–8) includes an atrial septectomy and transection and ligation of the distal main pulmonary artery; the proximal pulmonary artery is then connected to the transversely opened hypoplastic aortic arch to form a neoaorta, and the coarcted segment of the aorta is repaired. A synthetic aortopulmonary shunt connects the aorta to the main pulmonary artery to provide controlled pulmonary blood flow. The operative risk for the first-stage Norwood procedure is high and varies greatly among centers, although the best reported results demonstrate a better than 85–90% survival rate.

The second stage consists of a Glenn anastomosis to connect the superior vena cava to the pulmonary arteries (see Chapter 423.4), followed by a modified Fontan procedure (cavopulmonary isolation) to connect the inferior vena cava to the pulmonary arteries via either an intra-atrial or external baffle. After the third stage, all systemic venous return enters the pulmonary circulation directly. Pulmonary venous flow enters the left atrium and is directed across the atrial septum to the tricuspid valve and subsequently to the right (now the systemic) ventricle. Blood leaves the right ventricle via the neoaorta, which supplies the systemic circulation. The old aortic root now attached to the neoaorta provides coronary blood flow. The risks associated with stages II and III are considerably less than those of

Figure 424.10-8 Current technique for first-stage palliation of hypoplastic left heart syndrome. *A*, Incisions used for the procedure incorporate a cuff of arterial wall allograft. The distal divided main pulmonary artery may be closed by direct suture or with a patch. *B*, Dimensions of the cuff of the arterial wall allograft. *C*, The arterial wall allograft is used to supplement the anastomosis between the proximal divided main pulmonary artery and the ascending aorta, aortic arch, and proximal descending aorta. *D* and *E*, The procedure is completed by an atrial septectomy and a 3.5?mm modified right Blalock shunt. *F*, When the ascending aorta is particularly small, an alternative procedure involves placement of a complete tube of arterial allograft. The tiny ascending aorta may be left in situ, as indicated, or implanted into the side of the neoaorta. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: Single-ventricle tricuspid atresia. In *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

stage I; the long-term results of the Norwood procedure remain to be demonstrated.

An alternative therapy is *cardiac transplantation*, either in the immediate neonatal period, thereby obviating stage I of the Norwood procedure, or after a successful stage I Norwood procedure is performed as a bridge to transplantation. After transplantation, patients usually have normal cardiac function and no symptoms of heart failure; however, these patients have the chronic risk of organ rejection and lifelong immunosuppressive therapy (see Chapter 435.1). The combination of donor shortage and good results with the Norwood procedure has caused many centers to stop recommending transplantation except when associated lesions make the Norwood operation an exceptionally high-risk procedure.

424.11 Abnormal Positions of the Heart and the Heterotaxy Syndromes (Asplenia, Polysplenia)

Classification and diagnosis of abnormal cardiac position are best performed via a segmental approach, with the position of the viscera and atria first identified, then the ventricles, followed by the great vessels. Determination of *visceroatrial situs* can be made by roentgenographic demonstration of the position of the abdominal organs and the tracheal bifurcation for recognition of the right and left bronchi and by *echocardiography*. The atrial situs is related to the situs of the viscera and lungs. In **situs solitus**, the viscera are in their normal positions (stomach and spleen on the left, liver on the right), the three-lobed right lung is on the right, and the two-lobed left lung on the left; the right atrium is on the right, whereas the left atrium is on the left. When the abdominal organs and lungs are reversed, an arrangement known as **situs inversus**, the left atrium is on the right and the right atrium on the left. If the visceroatrial situs cannot be readily determined, a condition known as **situs indeterminus** or **heterotaxia** exists. The two major variations are (1) **asplenia syndrome** (right isomerism or bilateral right-sidedness), which is associated with a centrally located liver, absent spleen, and two morphologic right lungs, and (2) **polysplenia syndrome** (left isomerism or bilateral left-sidedness), which is associated with multiple small spleens, absence of the intrahepatic portion of the inferior vena cava, and bilateral left lung morphology (i.e., in both lungs). The heterotaxia syndromes are usually associated with severe congenital heart lesions: ASD, VSD, atrioventricular septal defect, pulmonary stenosis or atresia, and anomalous systemic venous or pulmonary venous return (Table 424–2).

The next segment is *localization of the ventricles*, which depends on the direction of development of the embryonic cardiac loop. Initial protrusion of the loop to the right (**d-loop**) carries the future right ventricle to the right, whereas the left ventricle remains on the left. With situs solitus, this arrangement yields normal atrioventricular connections (right atrium connecting to the right ventricle, left atrium to the left ventricle). Protrusion of the loop to the left (**l-loop**) carries the future right ventricle to the left and the left ventricle to the right. In this case, in the presence of situs solitus, the right atrium connects with the left ventricle and the left atrium with the right ventricle (**ventricular inversion**).

TABLE 424.11-2 -- Comparison of Cardiosplenic Heterotaxy Syndromes

Feature	Asplenia (Right Isomerism)	Polysplenia (Left Isomerism)
Spleen	Absent	Multiple
Sidedness (isomerism)	Bilateral right	Bilateral left
Lungs	Bilateral trilobar with eparterial bronchi	Bilateral bilobar with hyparterial bronchi
Sex	Male (65%)	Female = male
Right-sided stomach	Yes	Less common
Symmetric liver	Yes	Yes
Partial intestinal rotation	Yes	Yes
Dextrocardia (%)	30–40	30–40
Pulmonary blood flow	Decreased (usually)	Increased (usually)
Severe cyanosis	Yes	No

Transposition of great arteries (%)	60–75	15
Total anomalous pulmonary venous return (%)	70–80	Rare
Common atrioventricular valve (%)	80–90	20–40
Single ventricle (%)	40–50	10–15
Absent inferior vena cava with azygos continuation	No	Characteristic
Bilateral superior vena cava	Yes	Yes
Other common defects	PA, PS	Partial anomalous pulmonary venous return, ventricular septal defect, double-outlet right ventricle
Risk of sepsis	Yes	No
Howell-Jolly and Heinz bodies, pitted erythrocytes	Yes	No
Absent gallbladder; biliary atresia	No	Yes
Mortality	High	Moderately high if symptomatic

PA = pulmonary atresia; PS = pulmonary stenosis.

The final segment is that of the *great vessels*. With each type of cardiac loop, the ventricular-arterial relationships may be regarded as either normal (right ventricle to the pulmonary artery, left ventricle to the aorta) or transposed (right ventricle to the aorta, left ventricle to the pulmonary artery). A further classification can be based on the position of the aorta (normally to the right and posterior) relative to the pulmonary artery. In transposition, the aorta is usually anterior and either to the right of the pulmonary artery (**d-transposition**) or to the left (**l-transposition**). These segmental relationships can be determined by *echocardiographic* and *angiographic* studies demonstrating both atrioventricular and ventriculoarterial relationships. The clinical manifestations of these syndromes of abnormal cardiac position are determined primarily by their associated cardiovascular anomalies.

Dextrocardia occurs when the heart is in the right side of the chest; **levocardia** (the normal situation) is present when the heart is in the left side of the chest. *Dextrocardia without associated situs inversus* and *levocardia in the presence of situs inversus* are most often complicated by severe malformations that include various combinations of single ventricle, arterial transposition, pulmonary stenosis, ASDs and VSDs, atrioventricular septal defect, anomalous pulmonary venous return, tricuspid atresia, and pulmonary arterial hypoplasia or atresia. Surveys of older children and adults indicate that dextrocardia with situs inversus and normally related great arteries (so-called *mirror-image dextrocardia*) is often associated with a functionally normal heart, although congenital heart disease of a less severe nature is common.

Anatomic or functional abnormalities of the lungs, diaphragm, and thoracic cage may result in displacement of the heart to the right (**dextroposition**). However, in this case the *cardiac apex* is pointed normally to the left. This anatomic position is less often associated with congenital heart lesions, although hypoplasia of a lung may be accompanied by anomalous pulmonary venous return from that lung (scimitar syndrome).

The *electrocardiogram* is difficult to interpret in the presence of lesions with discordant atrial, ventricular, and great vessel anatomy. Diagnosis usually requires detailed *echocardiographic* and *cardiac catheterization* studies. The prognosis and treatment of patients with one of the cardiac positional anomalies are determined by the underlying defects. Asplenia increases the

risk of serious infections such as bacterial sepsis and thus requires daily antibiotic prophylaxis. The risk of sudden death from arrhythmias after palliative surgery is also increased. **REFERENCES**

Chapter 425 - Other Congenital Heart and Vascular Malformations

425.1 Anomalies of the Aortic Arch

Right Aortic Arch.

In this abnormality, the aorta curves to the right and, if it descends on the right side of the vertebral column, is usually associated with other cardiac malformations. It is found in 20% of cases of tetralogy of Fallot and is common in truncus arteriosus. A right aortic arch without other cardiac anomalies is not associated with symptoms. It can often be visualized on the chest roentgenogram. The trachea is deviated to the left of the midline rather than to the right, as in the presence of a normal left arch. On a barium esophagogram, the esophagus is indented on its right border at the level of the aortic arch.

Vascular Rings.

Congenital abnormalities of the aortic arch and its major branches result in the formation of vascular rings around the trachea and esophagus with varying degrees of compression. Common anomalies include (1) double aortic arch (Fig. 425–1*A*), (2) right aortic arch with a left ligamentum arteriosum, (3) anomalous innominate artery arising further to the left on the arch than usual, (4) anomalous left carotid artery arising further to the right than usual and passing anterior to the trachea, and (5) anomalous left pulmonary artery (vascular sling). In the latter anomaly, the abnormal vessel arises from an elongated main pulmonary artery or from the right pulmonary artery. It courses between and compresses the trachea and the esophagus. Associated congenital heart disease may be present in 5–50% of patients, depending on the vascular anomaly.

Clinical Manifestations.

If the vascular ring produces compression of the trachea and esophagus, symptoms are frequently present during infancy. Chronic wheezing is exacerbated by crying, feeding, and flexion of the neck. Extension of the neck tends to relieve the noisy respiration. Vomiting is frequent. Affected infants may have a brassy cough, pneumonia, or sudden death from aspiration.

Diagnosis.

Roentgenographic examination of the barium-filled esophagus (Fig. 425–2) and aortography identify the anomaly. An aberrant right subclavian artery is commonly seen but does not cause compression of the trachea. The diagnosis is confirmed by two-dimensional echocardiography, MRI, CT, or angiography during cardiac catheterization. Bronchoscopy may be used to determine the extent of airway narrowing.

Treatment.

Surgery is advised for symptomatic patients who have roentgenographic evidence of tracheal compression. The anterior vessel is usually divided in patients with a double aortic arch (see Fig. 425–1*B*). Compression produced by a right aortic arch and left ligamentum arteriosum is relieved by division of the latter. Anomalous innominate or carotid arteries cannot be divided; the tracheal compression is usually relieved by attaching the adventitia of these vessels to the sternum. An anomalous left pulmonary artery is corrected during cardiopulmonary bypass by division at its origin and re-anastomosis to the main pulmonary artery after it has been brought in front of the trachea. Severe tracheomalacia may be present and require reconstruction of the trachea as well.

425.2 Anomalous Origin of the Coronary Arteries

ANOMALOUS ORIGIN OF THE LEFT CORONARY ARTERY FROM THE PULMONARY ARTERY

In anomalous origin of the left coronary artery from the pulmonary artery, the blood supply to the left ventricular myocardium is severely compromised. Soon after birth, as pulmonary arterial pressure falls, perfusion pressure to the left coronary artery becomes inadequate; myocardial ischemia, infarction, and fibrosis result. In some cases, interarterial collateral anastomoses develop between the right and left coronary arteries. Blood flow in the left coronary artery is then reversed, and it empties into the pulmonary artery, a condition known as the “myocardial steal” syndrome. The left ventricle becomes dilated, and performance is decreased. Mitral insufficiency is a frequent complication secondary to a dilated valve ring or infarction of a papillary muscle. Localized aneurysms may also

Figure 425.2-1 Double aortic arch. *A*, Small anterior segment of the double aortic arch (most common type). *B*, Operative procedure for release of the vascular ring.

develop in the left ventricular free wall. Occasional patients have adequate myocardial blood flow during childhood and, later in life, a continuous murmur and a small left-to-right shunt via the dilated coronary system (aorta to right coronary to left coronary to pulmonary artery).

Clinical Manifestations.

Evidence of heart failure becomes apparent within the 1st few months of life, and it is often precipitated by respiratory infection. Recurrent attacks of discomfort, restlessness, irritability, sweating, dyspnea, and pallor with or without mild cyanosis occur and probably represent angina pectoris. Cardiac enlargement is moderate to massive. A gallop rhythm is common. If a gallop is present, murmurs may be of the nonspecific, ejection type or may be holosystolic and due to mitral insufficiency. Older patients with abundant intercoronary anastomoses may have continuous murmurs and minimal left ventricular dysfunction. During adolescence, they may experience angina during exercise. Rare patients with an anomalous right coronary artery may also have such clinical findings.

Diagnosis.

Roentgenographic examination confirms the cardiomegaly. The *electrocardiogram* resembles the pattern described in lateral wall myocardial infarction in adults. A QR pattern followed by inverted T waves is seen in leads I and aVL. The left ventricular surface leads (V_5 and V_6) may also show deep Q waves and exhibit elevated ST segments and inverted T waves (Fig. 425–3). In older patients, an exercise study may be helpful as ST-T wave changes or symptoms occur. *Two-dimensional echocardiography* may suggest the diagnosis; echocardiography is not always reliable in diagnosing this condition. On two-dimensional imaging alone, the left coronary artery can appear as though it were arising from the aorta. Color Doppler ultrasound examination has improved the accuracy of diagnosis of this lesion and may demonstrate retrograde flow in the left coronary artery. *Cardiac catheterization* is diagnostic; *aortography* shows immediate opacification of the right coronary artery only. This vessel is large and tortuous. After filling of the intercoronary anastomoses, the left coronary artery is opacified, and contrast can be seen to enter the pulmonary artery. Pulmonary arteriography may also opacify the origin of the anomalous left coronary artery. Selective left ventriculography usually demonstrates a dilated left ventricle that empties poorly.

Treatment and Prognosis.

Untreated, death often occurs from heart failure within the 1st 6 mo. Those who survive generally have abundant intercoronary collateral anastomoses. Medical management includes standard therapy for heart failure (diuretics, digoxin, captopril) and for controlling ischemia (nitrates, b-blocking agents).

Surgical treatment consists of detaching the anomalous coronary artery from the pulmonary artery and anastomosing it to the aorta to establish normal myocardial perfusion. A seriously ill infant with a tiny left coronary artery may present a difficult technical problem. Ligation of the anomalous left coronary artery at its origin was once performed to prevent runoff from the coronary circuit and possibly to increase myocardial perfusion by the collateral circulation. This operation may occasionally be required. In patients who have already sustained a significant myocardial infarction, cardiac transplantation is another option.

ANOMALOUS ORIGIN OF THE RIGHT CORONARY ARTERY FROM THE PULMONARY ARTERY

Anomalous origin of the right coronary artery from the pulmonary artery is rarely manifested in infancy or early childhood. The left coronary artery is enlarged, whereas the right is thin walled and mildly enlarged. In early infancy, perfusion of the right coronary artery is from the pulmonary artery, whereas later, perfusion is from collaterals of the left coronary vessels. Angina and sudden death can occur in adolescence or adulthood. When recognized, this anomaly should be repaired by re-anastomosis of the right coronary artery to the aorta.

ECTOPIC ORIGIN OF THE CORONARY ARTERY FROM THE AORTA WITH ABERRANT PROXIMAL COURSE

In ectopic origin of the coronary artery from the aorta with an aberrant proximal course, the aberrant artery may be a left, right, or major branch coronary artery. The site of origin may be the wrong sinus of Valsalva or a proximal coronary artery. The ostium may be hypoplastic, slitlike, or of normal caliber. The aberrant vessel may pass anteriorly, posteriorly, or between the aorta and right ventricular outflow tract; it may tunnel in the conal or interventricular septal tissue. Obstruction resulting from hypoplasia of the ostia, tunneling between the aorta and right ventricular outflow tract or interventricular septum, and acute angulation produces focal myocardial fibrosis or myocardial infarction. Unobstructed vessels produce no symptoms. Patients with this extremely rare abnormality are often initially seen with severe myocardial infarction, ventricular arrhythmias, angina pectoris, or syncope; sudden death may occur in young adult or adolescent athletes.

Figure 425.2-2 Double aortic arch in an infant aged 5 mo. *A*, Anteroposterior view. The barium-filled esophagus is constricted on both sides. *B*, Lateral view. The esophagus is displaced forward. The anterior arch was the smaller and was divided at surgery.

Diagnosis should include an electrocardiogram, stress testing, two-dimensional echocardiography, and cardiac catheterization with selective coronary angiography.

Treatment is indicated for obstructed vessels and consists of aortoplasty with re-anastomosis of the aberrant vessel or, occasionally, coronary artery bypass grafting.

425.3 Pulmonary Arteriovenous Fistula

Fistulous vascular communications in the lungs may be large and localized or multiple, scattered, and small. The most common form of this unusual condition is the **Osler-Weber-Rendu syndrome** (hereditary hemorrhagic telangiectasia type I), which is also associated with angiomas of the nasal and buccal

Figure 425.3-3 Electrocardiogram of a 3-mo-old child with anomalous origin of the left coronary artery

from the pulmonary artery. Lateral myocardial infarction is present as evidenced by abnormally large and wide Q waves in leads I, V_5, and V_6; an elevated ST segment in V_5 and V_6; and inversion of TV_6.

mucous membranes, gastrointestinal tract, or liver. This syndrome is caused by mutations in the endoglin gene, a cell surface component of the transforming growth factor-b receptor complex. The usual communication is between the pulmonary artery and pulmonary vein; direct communication between the pulmonary artery and left atrium is extremely rare. Desaturated blood in the pulmonary artery is shunted through the fistula into the pulmonary vein, thus bypassing the lungs, and then enters the left side of the heart; this aberrant direction of flow results in systemic arterial desaturation and, sometimes, clinical cyanosis. The shunt across the fistula is at low pressure and resistance, so pulmonary arterial pressure is normal; cardiomegaly and heart failure are not present.

The *clinical manifestations* depend on the magnitude of the shunt. Large fistulas are associated with dyspnea, cyanosis, clubbing, a continuous murmur, and polycythemia. Hemoptysis is

rare, but when it occurs, it may be massive. Features of the Osler-Weber-Rendu syndrome are seen in about 50% of patients (or other family members) and include recurrent epistaxis and gastrointestinal tract bleeding. Transitory dizziness, diplopia, aphasia, motor weakness, or convulsions may result from cerebral thrombosis, abscess, or paradoxical emboli. Soft systolic or continuous murmurs may be audible over the site of the fistula. The electrocardiogram is normal. Roentgenographic examination of the chest may show opacities produced by large fistulas; multiple small fistulas may be visualized by fluoroscopy (as abnormal pulsations), MRI, or CT. Selective pulmonary arteriography demonstrates the site, extent, and distribution of the fistulas.

Treatment consisting of excision of solitary or localized lesions by lobectomy or wedge resection results in complete disappearance of symptoms. In most instances, fistulas are so widespread that surgery is not possible. Direct communication between the pulmonary artery and the left atrium, if present, can be obliterated by division and suture.

Patients who have undergone a *Glenn cavopulmonary anastomosis* for cyanotic congenital heart disease are also at risk for the development of pulmonary arteriovenous malformations. In these patients the arteriovenous malformations are usually multiple and the risk increases over time after the Glenn procedure. These malformations rarely occur after the heart disease is fully palliated by completion of the Fontan operation. The pulmonary circulation may require an unknown hepatic factor to suppress the development of arteriovenous malformations. The hallmark of the development of these malformations is a decrease in the patient's oxygen saturation. The diagnosis can often be made with contrast echocardiography; cardiac catheterization is the definitive test. Completion of the Fontan circuit so that inferior vena cava blood flow is routed through the lungs results in improvement or resolution of the malformations.

425.4 Ectopia Cordis

In the most common thoracic form of ectopia cordis, the sternum is split and the heart protrudes outside the chest. In other forms, the heart protrudes through the diaphragm into the abdominal cavity or may be situated in the neck. Associated intracardiac anomalies are common. Death occurs in the 1st days of life in most, usually from infection, cardiac failure, or hypoxemia. Surgical therapy for neonates without overwhelmingly severe cardiac anomalies consists of covering the heart with skin without compromising venous return or ventricular ejection. Palliation of associated defects is also often necessary. Occasional patients with the abdominal type have survived to adulthood.

425.5 Diverticulum of the Left Ventricle

In this rare anomaly, a diverticulum of the left ventricle protrudes into the epigastrium. The lesion may be isolated or associated with complex cardiovascular anomalies. A pulsating mass is visible and palpable in the epigastrium. Systolic or systolic-diastolic murmurs produced by blood flow into and out of the diverticulum may be audible over the lower part of the sternum and the mass. The *electrocardiogram* shows a pattern of complete or incomplete left bundle branch block. *Roentgenograms* of the chest may or may not show the mass. Associated abnormalities include defects of the sternum, abdominal wall, diaphragm, and pericardium. Surgical treatment of the diverticulum and associated cardiac defects can be performed in selected cases. Occasionally, a diverticulum may be small and not associated with clinical signs or symptoms. These small diverticula are diagnosed at the time of echocardiographic examination for other indications.

Chapter 426 - Pulmonary Hypertension

426.1 Primary Pulmonary Hypertension

Pathophysiology.

Primary pulmonary hypertension is characterized by pulmonary vascular obstructive disease and right-sided heart failure. It occurs at any age, although in pediatric patients the diagnosis is initially made in the teenage years. In older patients, females outnumber males 1.7:1; in younger patients, both genders are represented equally. Some patients have evidence of either an immunologic disorder or a hypercoagulable state. Mutations in the gene for bone morphogenetic protein receptor-II (a member of the transforming growth factor-ß receptor family) have been identified in patients with autosomal dominant familial primary pulmonary hypertension (known as *PPH1*). This genetic variant demonstrates anticipation and a female preponderance. Up to 25% of patients may have a mutation in this gene. Angiopoietin-1, an angiogenic factor, and its receptor are overexpressed in patients. Angiopoietin-1 inhibits expression of bone morphogenetic protein receptors. Diet pills, particularly fenfluramine, have also been implicated. Pulmonary hypertension is associated with precapillary obstruction of the pulmonary vascular bed as a result of hyperplasia of the muscular and elastic tissues and a thickened intima of the small pulmonary arteries and arterioles. Atherosclerotic changes may be found in the larger pulmonary arteries. In children, veno-occlusive disease may account for some cases of primary pulmonary hypertension. For the diagnosis other causes of elevated pulmonary pressure must be eliminated (chronic pulmonary parenchymal disease, persistent obstruction of the upper airway, congenital cardiac

malformations, recurrent pulmonary emboli, alveolar capillary dysplasia, liver disease, autoimmune disease, and moyamoya disease). Pulmonary hypertension places an afterload burden on the right ventricle, which results in right ventricular hypertrophy. Dilatation of the pulmonary artery is present, and pulmonary valve insufficiency may occur. In the later stages of the disease, the right ventricle dilates, tricuspid insufficiency develops, and cardiac output is decreased. Arrhythmias, syncope, and sudden death are common.

Clinical Manifestations.

The predominant symptoms include exercise intolerance and fatigability;

occasionally, precordial chest pain, dizziness, syncope, or headaches are noted. Peripheral cyanosis may be present, especially in patients with a patent foramen ovale through which blood can shunt from right to left; in the late stages of disease, patients may have cold extremities and a gray appearance associated with low cardiac output. Arterial oxygen saturation is usually normal. If right-sided heart failure has supervened, jugular venous pressure is elevated, and hepatomegaly and edema are present. Jugular venous *"a"* waves are present, and in those with functional tricuspid insufficiency, a conspicuous jugular *"cv"* wave and systolic hepatic pulsations are manifested. The heart is moderately enlarged, and a right ventricular heave can be noted. The 1st heart sound is often followed by an ejection click emanating from the dilated pulmonary artery. The 2nd heart sound is narrowly split, loud, and sometimes booming in quality; it is frequently palpable at the upper left sternal border. A presystolic gallop rhythm may be audible at the lower left sternal border. The systolic murmur is soft and short and is sometimes followed by a blowing decrescendo diastolic murmur caused by pulmonary insufficiency. In later stages, a holosystolic murmur of tricuspid insufficiency is appreciated at the lower left sternal border.

Diagnosis.

Chest roentgenograms reveal a prominent pulmonary artery and right ventricle (Fig. 426–1). The pulmonary vascularity in the hilar areas may be prominent, in contrast to the peripheral lung fields, in which pulmonary markings are decreased. The electrocardiogram shows right ventricular hypertrophy, often with spiked P waves.

At *cardiac catheterization* this condition must be differentiated from **Eisenmenger syndrome** (see Chapter 426.2), which is associated with a communication between the left and right sides of the heart or great arteries, as well as from left-sided obstructive lesions (pulmonary venous stenosis, mitral stenosis) that result in pulmonary venous hypertension (see Chapter 420). The presence of pulmonary artery hypertension with a normal pulmonary capillary wedge pressure is diagnostic of primary pulmonary hypertension. If the wedge pressure is elevated and left ventricular end-diastolic pressure is normal, obstruction at the level of the pulmonary veins, left atrium, or mitral valve should be suspected. The risks associated with cardiac catheterization may be high in severely ill patients with primary pulmonary hypertension.

Prognosis and Treatment.

Primary pulmonary hypertension is progressive, and no cure is currently available. Some success has been reported with oral calcium channel blocking agents such as nifedipine in children who demonstrate pulmonary vasoreactivity when these agents are administered during catheterization. Continuous intravenous infusion of prostacyclin (prostaglandin I_2) provides relief as long as the infusion is continued. Continuous administration of nitric oxide via nasal cannula, nebulized forms of prostacyclin, and orally administered pulmonary vasodilators (bosentan, an antagonist of endothelin receptors; or sildenafil, a phosphodiesterase type 5 inhibitor and generator of nitric oxide) are all being investigated. Anticoagulation may be of value in patients with previous pulmonary thromboemboli, and some of these patients will respond to balloon angioplasty of narrowed pulmonary artery

Figure 426.1-1 Roentgenogram in primary pulmonary hypertension. Note the moderate cardiac enlargement, dilatation of the pulmonary artery, and relative pulmonary undervascularity in the outer two thirds of the lung fields.

segments. Despite many advances, definitive therapy is still heart-lung or lung transplantation (see Chapter 435). In patients with severe pulmonary hypertension and low cardiac output, the terminal event is often sudden and related to a lethal arrhythmia. Patients with primary pulmonary hypertension diagnosed in infancy often have rapid progression and high mortality.

426.2 Pulmonary Vascular Disease (Eisenmenger Syndrome)

Pathophysiology.

The term *Eisenmenger syndrome* refers to patients with a ventricular septal defect in which blood is shunted partially or totally from right to left as a result of the development of pulmonary vascular disease. This physiologic abnormality can also occur with atrial septal defect, atrioventricular septal defect, patent ductus arteriosus, or any other communication between the aorta and pulmonary artery. Pulmonary vascular disease with an isolated atrial septal defect is less common and does not occur until late in adulthood.

In Eisenmenger syndrome, pulmonary vascular resistance after birth either remains high or, after having decreased during early infancy, rises thereafter because of increased shear stress on pulmonary arterioles. Factors playing a role in the rapidity of development of pulmonary vascular disease include increased pulmonary arterial pressure, increased pulmonary blood flow, and the presence of hypoxia or hypercapnia. Early in the course of disease, pulmonary hypertension (elevated pressure in the pulmonary arteries) is the result of markedly increased pulmonary blood flow (*hyperkinetic pulmonary hypertension*). This form of pulmonary hypertension decreases with the administration of pulmonary vasodilators or oxygen, or both. With the development of Eisenmenger syndrome, pulmonary hypertension is the result of *pulmonary vascular disease* (obstructive pathologic changes in the pulmonary vessels). This form of pulmonary hypertension is usually only minimally responsive to pulmonary vasodilators or oxygen or not at all.

Pathology and Pathophysiology.

The pathologic changes of Eisenmenger syndrome occur in the small pulmonary arterioles and muscular arteries (<300?mm) and are graded on the basis of

histologic characteristics (*Heath-Edwards classification*): grade I changes involve medial hypertrophy alone, grade II consists of medial hypertrophy and intimal hyperplasia, grade III involves near obliteration of the vessel lumen, grade IV includes arterial dilatation, and grades V and VI include plexiform lesions,

angiomatoid formation, and fibrinoid necrosis. Grades IV–VI indicate irreversible pulmonary vascular obstructive disease. Eisenmenger physiology is defined by an absolute elevation in pulmonary arterial resistance to greater than 12 Wood units (resistance units indexed to body surface area) or by a ratio of pulmonary to systemic vascular resistance of 1.0 or higher.

Pulmonary vascular disease occurs more rapidly in patients with trisomy 21 who have left-to-right shunts. It also complicates the natural history of patients with elevated pulmonary venous pressure secondary to mitral stenosis or left ventricular dysfunction, any patient with transmission of systemic pressure to the pulmonary circulation via a shunt at the interventricular or great vessel level, and patients chronically exposed to low P_{O_2} (because of high altitude). Patients with cyanotic congenital heart lesions associated with unrestricted pulmonary blood flow are at particularly high risk.

Clinical Manifestations.

Symptoms do not usually develop until the 2nd or 3rd decade of life, although a more fulminant course may occur. Many patients survive for decades with minimal symptoms. Intracardiac or extracardiac communications that would normally shunt from left to right are converted to right-to-left shunting as pulmonary vascular resistance exceeds systemic vascular resistance. Cyanosis becomes apparent, and dyspnea, fatigue, and a tendency toward dysrhythmias begin to occur. In the late stages of the disease, heart failure, chest pain, headaches, syncope, and hemoptysis may be seen. Physical examination reveals a right ventricular heave and a narrowly split 2nd heart sound with a loud pulmonic component. Palpable pulmonary artery pulsation may be present at the left upper sternal border. A holosystolic murmur of tricuspid regurgitation may be audible along the left sternal border. An early decrescendo diastolic murmur of pulmonary insufficiency may also be heard along the left sternal border. The degree of cyanosis depends on the stage of the disease.

Diagnosis.

Cyanotic patients have various degrees of polycythemia that depend on the severity and duration of hypoxia. *Roentgenographically*, the heart varies in size from normal to greatly enlarged; the latter usually occurs late in the course of the disease. The main pulmonary artery is generally prominent, similar to primary pulmonary hypertension (see Fig. 426–1).

TABLE 426.2-1 -- **Extracardiac Complications of Cyanotic Congenital Heart Disease and Eisenmenger Physiology**

Problem	Etiology	Therapy
Polycythemia	Persistent hypoxia	Phlebotomy
Relative anemia	Nutritional deficiency	Iron replacement
CNS abscess	Right-to-left shunting	Antibiotics, drainage
CNS thromboembolic stroke	Right-to-left shunting or polycythemia	Phlebotomy
Low-grade DIC, thrombocytopenia	Polycythemia	None for DIC unless bleeding, then phlebotomy
Hemoptysis	Pulmonary infarct, thrombosis, or rupture of pulmonary artery plexiform lesion	Embolization
Gum disease	Polycythemia, gingivitis, bleeding	Dental hygiene
Gout	Polycythemia, diuretic agent	Allopurinol
Arthritis, clubbing	Hypoxic arthropathy	None
Pregnancy complications: abortion, fetal growth retardation, prematurity, maternal illness	Poor placental perfusion, poor ability to increase cardiac output	Bed rest, pregnancy prevention counseling
Infections	Associated asplenia, DiGeorge syndrome, endocarditis	Antibiotics
	Fatal RSV pneumonia with pulmonary hypertension	Ribavirin; RSV immunoglobulin (prevention)
Failure to thrive	Increased oxygen consumption, decreased nutrient intake	Treat heart failure; correct defect early; increase caloric intake
Psychosocial adjustment	Limited activity, cyanotic appearance, chronic disease, multiple hospitalizations	Counseling

CNS = central nervous system; DIC = disseminated intravascular coagulation; RSV = respiratory syncytial virus.

The pulmonary vessels are enlarged in the hilar areas and taper rapidly in caliber in the peripheral branches. The right ventricle and atrium are prominent. The electrocardiogram shows marked right ventricular hypertrophy. The P wave may be tall and spiked.

The *echocardiogram* shows a thick-walled right ventricle and demonstrates the underlying congenital heart lesion. Two-dimensional echocardiography assists in eliminating from consideration lesions such as obstructed pulmonary veins, a supramitral membrane, and mitral stenosis. The pulmonary valve echocardiogram shows a characteristic early midsystolic closure, the “W sign.” Doppler studies demonstrate the direction of the shunt and the presence of a typical hypertension waveform in the main pulmonary artery. Tricuspid and pulmonary regurgitation can be used in the Doppler examination to estimate pulmonary arterial pressure.

Cardiac catheterization usually shows a bidirectional shunt at the site of the defect.

Systolic pressure is generally equal in the systemic and pulmonary circulations. Pulmonary capillary wedge pressure is normal unless a left-sided heart obstructive lesion or left ventricular failure is the cause of the pulmonary artery hypertension. Arterial oxygen saturation is decreased because of the magnitude of the right-to-left shunt. The response to vasodilator therapy (oxygen, nitroprusside, calcium channel blockers, prostacyclin, nitric oxide) may identify patients with hyperdynamic pulmonary hypertension. Selective angiocardiography can locate the site of the shunt, but these studies are usually avoided in such patients because of increased risk and the accuracy of echocardiography. Selective pulmonary artery injections may be necessary if pulmonary venous obstruction is suspected because of high wedge pressure and low left ventricular end-diastolic pressure.

Treatment.

The best management for patients who are at risk for the development of late pulmonary vascular disease is prevention by early surgical elimination of large intracardiac or great vessel communications during infancy. Some patients may be missed because they have not shown early clinical manifestations. Pulmonary vascular resistance never decreases substantially at birth in some of these infants, and therefore they never acquire enough left-to-right shunting to become clinically apparent. Such delayed recognition is a particular risk in patients with congenital heart disease who live at high altitude. It is also a risk in infants with trisomy 21, who have a propensity for earlier development of pulmonary vascular disease. Because of the high incidence of congenital heart disease associated with trisomy 21, many physicians recommend routine

echocardiography at the time of initial diagnosis, even in the absence of other clinical findings.

Medical treatment of Eisenmenger syndrome is entirely symptomatic (Table 426–1). Older children and adolescents with symptomatic polycythemia may be improved by cautious, repeated phlebotomies with volume replacement. Clinical trials in adults have described short-term benefits from chronic calcium channel blocker or prostacyclin therapy, but experience with these agents in children is minimal. Combined heart-lung or bilateral lung transplantation is the only surgical option for many of these patients (see Chapter 435).

Chapter 427 - General Principles of Treatment of Congenital Heart Disease

Most patients who have mild congenital heart disease require no treatment. The parents and child should be made aware that a normal life is expected and that no restriction of the child's activities is necessary. Overprotective parents may use the presence of a mild congenital heart lesion or even a functional heart murmur as a means to exert excessive control over their child's activities. Although fears may not be expressed overtly, the child may become anxious regarding early death or debilitation, especially when an adult member of the family acquires symptomatic heart disease. The family may have an unexpressed fear of sudden death, and the rarity of this manifestation should be emphasized in discussions directed at improving their understanding of the child's congenital heart defect. The difference between congenital heart disease and degenerative coronary disease in adults should be emphasized. General health maintenance, including a well-balanced, “heart-healthy” diet, aerobic exercise, and avoidance of smoking, should be encouraged.

Even patients with moderate to severe heart disease need not be markedly restricted in physical activity. Physical education should be modified appropriately to the child's capacity to participate. The extent of such modification can generally be determined best by exercise testing. Competitive sports for most of these patients should be discouraged. Patients with severe heart disease and decreased exercise tolerance usually tend to limit their own activities. Dyspnea, headache, and fatigability in cyanotic patients may be a sign of increasing hypoxemia and may require some limitation of activity in those for whom specific medical or surgical treatment is not available. Routine immunizations should be given, with the inclusion of influenza vaccine; patients who might be considered candidates for heart or heart-lung transplantation should not receive live-virus vaccinations just before transplantation.

Bacterial infections should be treated vigorously, but the presence of congenital heart disease is not an appropriate reason to use antibiotics indiscriminately. Prophylaxis against infective endocarditis should be carried out during dental procedures, during instrumentation of the urinary tract, and before lower gastrointestinal tract manipulation (see Table 429–2).

Cyanotic patients need to be monitored for a multitude of noncardiac manifestations of oxygen deficiency (Table 427–1). Treatment of iron deficiency anemia is important in cyanotic patients who show improved exercise tolerance and general well-being with adequate hemoglobin levels. These patients should also be carefully observed for excessive polycythemia. Cyanotic patients should avoid situations in which dehydration may occur, which leads to increased viscosity and increases the risk of stroke. Diuretics may need to be decreased or temporarily discontinued during episodes of acute gastroenteritis. High altitudes and sudden changes in the thermal environment should also be avoided. Phlebotomy with volume replacement should be carried out in symptomatic patients with severe polycythemia (hematocrit >65%); the use of routine phlebotomy in the absence of symptoms is controversial. Patients with severe congenital heart disease or a history of rhythm disturbance should be carefully monitored during anesthesia for even routine surgical procedures. Women with nonrepaired severe congenital heart disease should be counseled on the risks associated with childbearing and on the use of contraceptives and tubal ligation. Pregnancy may be extremely dangerous for patients with chronic cyanosis or pulmonary artery hypertension, or both. Women with mild to moderate heart disease and many of those who have had corrective surgery can have normal pregnancies.

Postoperative Management.

After successful open heart surgery, the severity of the congenital heart defect, the age and condition (nutritional status) of the patient before surgery, the events in the operating room, and the quality of the postoperative care influence the patient's course. Intraoperative factors that influence survival and that should be noted when a patient returns from the operating room include the duration of cardiopulmonary bypass, the duration of aortic cross-clamping (the time during which the heart is not being perfused), and the duration of profound hypothermia (generally used in infants: the period during which the entire body is not being perfused).

Immediate postoperative care should be provided in an intensive care unit staffed by a team of physicians, nurses, and technicians experienced with the unique problems encountered after open heart surgery. Preparation for postoperative monitoring begins in the operating room, where the anesthesiologist or surgeon places an arterial catheter to allow direct arterial pressure measurements and arterial sampling for blood gas determination. A central venous catheter is also placed for measuring central venous pressure and for infusions of cardioactive medications. In more complex cases, left atrial or pulmonary artery catheters may be inserted directly into these cardiac structures and used for pressure monitoring purposes. Flow-directed thermodilution monitoring (Swan-Ganz) catheters are sometimes used for monitoring pulmonary capillary wedge pressure and the cardiac index. Temporary pacing wires are placed on the atrium or ventricle, or both, in case temporary heart block

TABLE 427-1 -- **Systems Approach to Postoperative Care Following Surgery for Congenital Heart Disease**

System and Problem	Etiology	Treatment or Prevention
Nervous System		

Coma	Global ischemia	Monitor and treat increased intracranial pressure
	Prolonged anesthetic effect	Reverse anesthesia
	Hypoglycemia	Glucose
Focal lesions	Emboli (air, thrombi)	
Seizures	Metabolic (hyponatremia, hypoglycemia), ischemic, embolic disturbances	Phenytoin, correct metabolic disturbances
Diaphragm paralysis	Phrenic nerve injury	Respiratory care
Vocal cord paralysis	Traction on recurrent laryngeal nerve	Respiratory care
Horner syndrome	Dissection of subclavian artery with sympathetic chain injury	None
Paraplegia	Postcoarctation repair with spinal artery ischemia	Avoid ischemia
Pain	Surgical trauma	Fentanyl, morphine
Anxiety	Stress	Midazolam (Versed), diazepam (Valium)
Respiratory System		
ARDS postpump syndrome	Unknown; possible release of vasoactive substances by cardiopulmonary bypass	PEEP, mechanical ventilation, oxygen
Pulmonary edema	Heart failure, left-sided obstructions, fluid overload	Diuresis, PEEP, mechanical ventilation, inotropic agents
Pleural effusions	Hemothorax	Thoracocentesis
	Early serous effusion	Thoracocentesis
	Delayed postpericardiotomy syndrome	Anti-inflammatory agents
Chylothorax	Injury to thoracic duct	NPO or medium-chain triglyceride diet
		Rarely surgical ligation of thoracic duct
Atelectasis	Hypoventilation, poor cough	Chest physiotherapy, PEEP
Pneumonia	Aspiration, nosocomial, bacteremia	Identify bacterial-viral (respiratory syncytial virus) cause; specific antimicrobial therapy
Pulmonary hypertension	Repair of TAPVR, Norwood 1st stage, trisomy 21; prior preoperative pulmonary hypertension	Hyperventilation, hyperoxia, nitroprusside, prostaglandins, nitric oxide, ECMO
Stridor	Vocal cord edema, paralysis	Steroids, rarely tracheotomy
Cardiovascular System		
Bradycardia, sick sinus syndrome, atrioventricular block	Injury to interatrial or interventricular conduction system	Atropine, isoproterenol, pacemaker
Right bundle branch block	Right ventriculotomy	Atrial approach to ventricular septal defect repair or tetralogy of Fallot
Tachyarrhythmias	Supraventricular, junctional tachycardia	Antiarrhythmic agents
	Ventricular tachycardia	Defibrillation, antiarrhythmic agents
Poor cardiac output	Cardiogenic—right ventriculotomy or cardiac "stun" (prolonged pump and cross-clamp time) or infarction	Inotropic agents, support preload, reduce afterload, LVAD, ECMO
	Hypocalcemia	Calcium
	Hypovolemia	Support preload with fluids
Pericardial tamponade	Pericardial effusion, acute hemorrhage	Pericardiocentesis
	Serous postpericardiotomy syndrome	Anti-inflammatory agents
Hypertension	Stress or pain	Analgesia
	Postcoarctectomy syndrome	Nitroprusside
Mesenteric arteritis	Postcoarctectomy syndrome	NPO, nitroprusside
Renal-Metabolic System		
Prerenal oliguria	Hypovolemia	Fluid administration
	Poor cardiac output	Inotropic agents

Renal failure	Hypotension, prolonged pump–cross-clamp time, acute tubular necrosis	Improve blood pressure, diuretics, dialysis
Edema	Fluid resuscitation, capillary leak, poor cardiac output, elevated systemic venous pressure	Diuresis, inotropic agents
Hyponatremia	Dilutional, SIADH	Fluid restriction
	Diuretics	Fluid restriction
Hyperglycemia	Hypothermia, inhibition of insulin	None needed (usually), insulin
Hypoglycemia	Rebound following hyperglycemia, hepatic failure	Glucose infusion
Hematologic System		
Hemorrhage	Abnormal PT, PTT, thrombocytopenia	Correct coagulopathy
	Surgical leak	Reoperation, suture
Shunt thrombosis	Poor cardiac output, hypovolemia	Fluids, heparin, reoperation
Anemia (usually reflecting reduced blood volume)	Hemorrhage, hemolysis	Transfuse packed red blood cells
Graft-vs-host disease	Infusion of viable leukocytes to patients with DiGeorge syndrome	Irradiate blood products
Infectious Diseases		
Wound infection (cutaneous, costochondral, sternotomy, mediastinitis, vascular lines, chest tubes)	Contamination in operating room	Antibiotics
Endocarditis	*Staphylococcus epidermidis, Corynebacterium*, contamination in operating room	Antibiotics
Cystitis, pyelonephritis	Contamination of indwelling urinary catheter	Antibiotics, remove catheter
Hepatitis	Blood-borne: cytomegalovirus, Epstein-Barr virus, hepatitis B and C viruses	Screen blood products
Postperfusion syndrome (fever, hepatosplenomegaly, atypical lymphocytes, lymphadenopathy, transient rash)	Cytomegalovirus, Epstein-Barr virus	Screen blood products
Psychosocial Conditions		
Anxiety, separation	Age related, fears, etc.	Preparedness (videotape, play acting); parent visitation, sedation

ARDS = acute respiratory distress syndrome; PEEP = positive end-expiratory pressure; NPO = nothing per os (by mouth);TAPVR = total anomalous pulmonary venous return; ECMO = extracorporeal membrane oxygenation; LVAD = left ventricular assist device; SIADH = syndrome of inappropriate antidiuretic hormone; PT = prothrombin time; PTT = partial thromboplastin time.

occurs. Transcutaneous oximetry provides for continuous monitoring of arterial oxygen saturation.

Functional failure of one organ system may cause profound physiologic and biochemical changes in another (see Table 427–1). Respiratory insufficiency, for example, leads to hypoxia, acidosis, and hypercapnia, which in turn compromises cardiac, vascular, and renal function. The latter problems cannot be managed successfully until adequate ventilation is re-established. Thus, it is essential that the primary source of each postoperative problem be identified and treated.

Respiratory failure is a major postoperative complication encountered after open heart surgery. Cardiopulmonary bypass carried out in the presence of pulmonary congestion results in decreased lung compliance, copious tracheal and bronchial secretions, atelectasis, and increased breathing effort. Because fatigue and subsequently hypoventilation and acidosis may rapidly ensue, mechanical positive pressure endotracheal ventilation may be continued after open heart surgery for a minimum of several hours in relatively stable patients and for up to 2–3 days or longer in severely ill patients, especially infants. Patients with certain congenital heart lesions may also have airway abnormalities that could make extubation more difficult.

The electrocardiogram should be monitored continuously during the postoperative period. A change in heart rate may be the 1st indication of a serious complication such as hemorrhage, hypothermia, hypoventilation, or heart failure. *Cardiac rhythm disorders* must be diagnosed quickly because a prolonged untreated arrhythmia may add a severe hemodynamic burden to the heart in the critical early postoperative period (see Chapter 428). Injury to the heart's conduction system during surgery can result in postoperative *complete heart block*. This complication is usually temporary and is treated with surgically placed pacing wires that can later be removed. Occasionally, complete heart block is permanent. If heart block persists beyond 10–14 days postoperatively, insertion of a permanent pacemaker is required. Tachyarrhythmias are a more common problem in postoperative patients. Junctional ectopic tachycardia can be a particularly troublesome rhythm to manage (see

Chapter 428).

Heart failure with poor cardiac output (see Table 427–1) after cardiac surgery may be secondary to respiratory failure, serious arrhythmias, myocardial injury, blood loss, hypervolemia or hypovolemia, or a significant residual hemodynamic abnormality. Treatment specific to the cause should be instituted. Catecholamines, phosphodiesterase inhibitors, digoxin, nitroprusside and other afterload-reducing agents, and diuretics are the cardioactive agents most often used in patients with myocardial dysfunction in the early postoperative period (see Chapter 434). Postoperative pulmonary hypertension can be managed with inhaled nitric oxide. In patients who are unresponsive to standard pharmacologic treatment, various ventricular assist devices are available, depending on the patient's size. If pulmonary function is adequate, an intra-aortic balloon counterpulsation pump or an external or implantable left ventricular assist device may be used. If pulmonary function is inadequate, extracorporeal membrane oxygenation may be used. These extraordinary measures are helpful in maintaining the circulation until cardiac function improves, usually within 2–3 days. They have also been used with some success as a bridge to transplantation in patients with severe nonremitting postoperative cardiac failure.

Acidosis secondary to low cardiac output, renal failure, or hypovolemia must be prevented or promptly corrected. An arterial pH less than 7.3 may result in a decrease in cardiac output with an increase in lactic acid production and may be the forerunner of a series of arrhythmias or cardiac arrest.

Kidney function may be compromised by congestive heart failure and further impaired by prolonged cardiopulmonary bypass (see Table 427–1). Blood and fluid replacement, cardiac inotropic agents, and sometimes vasodilators will usually re-establish normal urine flow in patients with hypovolemia or cardiac failure. Dopamine is a useful inotropic agent because it also increases renal blood flow directly. Renal failure secondary to tubular injury may require temporary peritoneal dialysis or hemofiltration.

Neurologic abnormalities can develop after cardiopulmonary bypass, especially in the neonatal period. Seizures may occur when the patient awakens from sedation and can usually be controlled with phenytoin (Dilantin) or phenobarbital. In the absence of other neurologic signs, isolated seizures in the immediate postoperative period usually carry a good prognosis. Thromboembolism and stroke are rare, but serious complications of open heart surgery. Over the long term, both subtle and more substantial learning disabilities may develop. Patients who have undergone surgery entailing the use of cardiopulmonary bypass, especially in the newborn period, should be watched carefully during their early school years for signs of learning disabilities, which are often amenable to early remedial intervention.

The *postpericardiotomy syndrome* may occur toward the end of the 1st postoperative week or may sometimes be delayed until weeks or months after surgery. This febrile illness is characterized by fever, decreased appetite, listlessness, nausea, and vomiting. Chest pain is not always present, so a high index of suspicion should be maintained in any recently postoperative patient. Echocardiography is diagnostic. In most instances the postpericardiotomy syndrome is self-limited; however, when pericardial fluid accumulates rapidly, the potential danger of cardiac tamponade should be recognized (see Chapter 432). Rarely, arrhythmias may also occur.

Symptomatic patients usually respond to salicylates or indomethacin and bed rest. Occasionally, steroid therapy or pericardiocentesis is required. A prolonged illness or late recurrences are less usual.

Hemolysis of mechanical origin is seen rarely after repair of certain cardiac defects, for example, atrioventricular septal defects, or after the insertion of a mechanical prosthetic valve. It is due to unusual turbulence of blood at increased pressure. Reoperation may be necessary in rare patients with severe and progressive hemolysis who require frequent blood transfusions, but in most instances the problem slowly regresses.

Infection is another potential postoperative problem. Patients usually receive a broad-spectrum antibiotic for the initial postoperative period. Potential sites of infection include the lungs (generally related to postoperative atelectasis), the subcutaneous tissues at the incision site, the sternum, and the urinary tract (especially after an indwelling catheter has been in place). Sepsis with infective endocarditis is an infrequent complication but can be difficult to manage (see Chapter 429).

Section 4 - *Cardiac Arrhythmias*

Anne Dubin

Chapter 428 - Disturbances of Rate and Rhythm of the Heart

Pediatric arrhythmias may be transient or permanent, congenital (in a structurally normal or abnormal heart) or acquired (rheumatic fever, myocarditis), or caused by a toxin (diphtheria), cocaine, or theophylline or by proarrhythmic or antiarrhythmic drugs. Arrhythmias may be a sequela of surgical correction of congenital heart disease or a result of congenital metabolic disorders of mitochondria or fetal inflammation as in systemic lupus erythematosus (SLE). The major risk of any arrhythmia is either severe tachycardia or bradycardia leading to decreased cardiac output or degeneration into a more critical arrhythmia such as ventricular fibrillation. These complications may lead to syncope, which itself can be dangerous under certain circumstances (e.g., swimming, driving), or to sudden death. When a patient has an arrhythmia, it is vital to determine whether the particular rhythm is prone to deteriorate into a life-threatening tachyarrhythmia or bradyarrhythmia. Some rhythm abnormalities, such as single premature atrial and ventricular beats, are common in children without heart disease and in the great majority of instances do not pose a risk to the patient.

A number of powerful pharmacologic agents are available for treating dysrhythmias in adults, but many have not been studied extensively in children. Problems with frequency of administration, compliance, side effects, drug interactions, and variable responses remain, and selection of an appropriate agent involves empiricism. Fortunately, the majority of rhythm disturbances in children can be reliably controlled with a single agent (Table 428–1). Transcatheter radiofrequency ablation is used not only for resistant tachyarrhythmias but also for elective definitive treatment of arrhythmias. For patients with bradyarrhythmias, implantable pacemakers are small enough for use in premature infants. Implantable cardioverter-defibrillators (ICDs) are available for use in high-risk patients with malignant ventricular arrhythmias and an increased risk of sudden death.

428.1 Sinus Arrhythmias and Extrasystoles

Sinus arrhythmia represents a normal physiologic variation in impulse discharges from the sinus node related to respirations. The heart rate slows during expiration and accelerates during inspiration. Occasionally, if the sinus rate becomes slow enough, an escape beat arises from the atrioventricular (AV) junction region (Fig. 428–1). Irregularities in sinus rhythm are commonly seen in premature infants, especially bradycardia associated with periodic apnea. Sinus arrhythmia is exaggerated during febrile illnesses and by drugs that increase vagal tone, such as digitalis; it is usually abolished by exercise.

Sinus bradycardia is due to slow discharge of impulses from the sinus node. A sinus rate less than 90 beats/min in neonates and less than 60 beats/min thereafter is considered to be sinus bradycardia. It is commonly seen in athletes; in healthy individuals it is without significance. Sinus bradycardia may occur in systemic disease, for example, myxedema, and it resolves when the disorder is under control. Sinus bradycardia must be differentiated from sinoatrial and AV block. Children with sinus bradycardia are able to increase their heart rate with exercise to much higher than 100 beats/min, whereas patients with AV block are usually unable to do so. Low-birthweight infants display great variation in sinus rate. Sinus bradycardia is common in these infants and may be associated with junctional escape beats. Premature atrial contractions are also frequent. These rhythm changes, especially bradycardia, appear more commonly during sleep and are not associated with symptoms. No therapy is usually necessary.

Wandering atrial pacemaker (Fig. 428–2) is defined as an intermittent shift in the pacemaker of the heart from the sinus node to another part of the atrium. It is not uncommon in childhood and usually represents a normal variant, but it may also be seen in patients with central nervous system disturbances, for example, subarachnoid hemorrhage.

Extrasystoles are produced by the discharge of an ectopic focus that may be situated anywhere in atrial, junctional, or ventricular tissue. Usually, isolated extrasystoles are of no clinical or prognostic significance. Under certain circumstances, however, premature beats may be due to organic heart disease (inflammatory, ischemic, fibrotic, and so on) or to drug toxicity, especially from digitalis.

TABLE 428.1-1 -- Antiarrhythmic Drugs Comn

Drug	Indications	Oral Administration		Intravenous Administration	
		Maintenance Dose	*Maximal Maintenance Dose*	*Loading Dose*	
Class IA: Inhibit Na⁺ Fast Channel, Prolong Repolarization					
Quinidine sulfate	SVT,[‡] atrial fibrillation, atrial flutter, VPC Digoxin, verapamil, or propranolol must be given first to prevent 1:1 conduction and fast ventricular rate in atrial flutter	20–60?mg/kg/ 24?hr q6h	2.4?g/24?hr	—	
Quinidine gluconate	Digoxin, verapamil, or propranolol must be given first to prevent 1:1 conduction and fast ventricular rate in atrial flutter	20–60?mg/kg/ 24?hr q8–12h	2.0?g/24?hr	—	
Procainamide	SVT,[‡] atrial fibrillation, atrial flutter, VPC, ventricular tachycardia[‡]	15–50?mg/kg/ 24?hr q4h or q6h[§]	4.0?g/24?hr	3–6?mg/kg over 5?min; repeat to 15?mg/kg/ load	
Disopyramide	SVT,[‡] atrial fibrillation, atrial flutter, VPC	< 2 yr: 20–30?mg/kg/24?hr divided q6h or q12?h for long acting form 2–10 yr: 9–24?mg/ kg/24?hr divided q6h or q12h for long acting form = 11 yr: 5–13?mg/kg/24?hr divided q6h or q12h for long acting form	1.2?g/24?hr	—	

Class IB: Inhibit Na^+ Fast Channel, Shorten Repolarization				
Lidocaine (class IB)	VPC, ventricular tachycardia,[‡] ventricular fibrillation	—	—	1?mg/kg; repeat q5?min 2 times
Mexilitene	VT, VPCs, ?long QT	6–15?mg/kg/ 24?hr, divided q24?hr	—	—
Phenytoin (class IB)	Digoxin-induced arrhythmias with heart block	3–6?mg/kg/ 24?hr q12h	600?mg	10–15?mg/ kg over 1?hr
Class II: ß-Blockers				
Propranolol	SVT,[†] PVCs, LQTS	1–4?mg/kg/ 24?hr q6h	16?mg/kg/ 24?hr or 60?mg/24?hr	0.1–0.15?mg/ kg over 5?min
Class III: Prolong Repolarization				
Amiodarone	Drug-resistant SVT, JET (congenital or postoperative), VT	Loading dose: 10?mg/kg/ 24?hr in 1–2 divided doses for 4–14 days; reduce to 5?mg/kg/24?hr for several weeks; if no recurrence, reduce to 2.5?mg/kg/ 24?hr; may be given for 5 of 7 days/wk	Adult doses: loading = 800–1600?mg/24?hr for 2 wk, then 600–800?mg/ 24?hr for 1 mo, then 400?mg/ 24?hr	Loading dose: 2.5–5?mg/kg over 30–60?min, may repeat 3 times; then 2–10?mg/kg/ 24?hr q24h
Class IV: Miscellaneous				
Digoxin (digitalis glycoside)	SVT [†] (non-WPW), atrial flutter, atrial fibrillation	10?µg/kg 24?hr q12h	0.5?mg	IV dose = 3/4 PO dose
Verapamil (Ca^{2+} channel blocker)	SVT [†]	2–7?mg/kg/ 24?hr q8h	480?mg	0.1–0.2?mg/ kg q20min 2 times (have IV $CaCl_2$ ready)
Adenosine (purinergic agonist)	SVT [†]	—	—	50–300?µg/kg begin with 50?µg/kg and increase by 50–100?µg/kg/ dose if no effect; 6–12?mg in adolescents

SVT = supraventricular tachycardia; VPC = ventricular premature contraction; AV = atrioventricular central nervous system; PVCs = premature ventricular complexes; LQTS = long QT syndrome; CH tachycardia; WPW = Wolff- Parkinson- White (pre-excitation) syndrome; IV = intravenous; PO = or

**IV administration of antiarrhythmic drugs should always be at a slow rate, with constant monitoring of blood pressure and an electrocardiogram, particularly in patients with compromised cardiac, renal, or*

hepatic function. The dose must be modified in patients with abnormal renal or hepatic function. The exception is adenosine, which must be given by rapid IV push, usually followed by a saline flush. It is generally ineffective if given intra-arterially.
† Vagotonic maneuvers (placing the face in iced saline or an ice bag over the face) may be attempted first. If the patient is severely compromised and critically ill, synchronized DC cardioversion is the treatment of choice for SVT, atrial flutter, and atrial fibrillation.
‡ Cardioversion is the treatment of choice for sustained VT with significant hemodynamic compromise. Some cardiologists try a chest thump or IV lidocaine, or both. If heart block is present, a temporary ventricular pacemaker may be needed.
§ Sustained- release preparations available for clinical use.
Defibrillation is the treatment of choice.

Figure 428.1-1 Sinus arrhythmia with a junctional escape beat. Note the variation in P-P interval with little change in P morphology or P-R interval. When the sinus rate is slow enough, the atrioventricular junction takes over and produces escape beats. This rhythm is normal.

Figure 428.1-2 Wandering atrial pacemaker. Note the change in P-wave configuration in the 7th, 9th, and 10th beats. The 7th P wave may represent a fusion between the sinus P and the ectopic atrial pacemaker seen in the 10th beat.

Premature atrial complexes are common in childhood, even in the absence of cardiac disease. Depending on the degree of prematurity of the beat (coupling interval) and the preceding R-R interval (cycle length), premature atrial complexes may result in a normal, a prolonged (*aberrancy*), or an absent (*blocked premature atrial complex*) QRS complex. The last occurs when the premature impulse is conducted to the ventricle while the specialized ventricular conducting system is partially refractory (Fig. 428–3). Atrial extrasystoles must be distinguished from premature ventricular complexes (PVCs). Careful scrutiny of the electrocardiogram for a premature P wave preceding the QRS that has a different contour from that of the other sinus P waves is essential for diagnosis. Atrial premature complexes often reset the sinus node pacemaker (lack of a compensatory pause), but this feature is not regarded as a reliable means of differentiating atrial from ventricular premature complexes.

PVCs may arise in any region of the ventricles. They are characterized by premature, widened, bizarre QRS complexes that are not preceded by a P wave (Fig. 428–4). When all premature beats have identical contours, they are classified as unifocal in origin. When PVCs vary in contour, they are designated as multifocal. Ventricular extrasystoles are often, but not always followed by a compensatory pause. The presence of fusion beats, that is, complexes with morphologic features that are intermediate between those of normal sinus beats and those of PVCs, is a clue to the ventricular origin of the extrasystole. Extrasystoles produce a smaller stroke and pulse volume than normal and, if quite premature, may not be audible with a stethoscope or palpable at the radial pulse. When frequent, extrasystoles may assume a definite rhythm, for example, alternating with normal beats (**bigeminy**) or occurring after two normal beats (**trigeminy**). Most patients are unaware of single premature ventricular contractions, although some may be aware of a “skipped beat” over the precordium. This sensation is due to the increased stroke volume of the normal beat following a compensatory pause. Anxiety, a febrile illness, or ingestion of

Figure 428.1-3 Premature atrial contraction (PAC). QRS complexes—the 8th, 10th, and final—in this strip are preceded by a P wave that is inverted, indicative of an ectopic origin of atrial depolarization. Note that the 8th and final QRS complexes resemble those of sinus origin whereas the 10th is aberrantly conducted. This shift in origin is a function of the preceding cycle length, which influences the refractory period of the bundle branches. The fact that the pause after the PAC is longer than two P-P intervals implies that the premature atrial depolarization has invaded and discharged the sinus node and then reset it so that it fires later.

Figure 428.1-4 Premature ventricular contractions (PVCs) induced by hyperventilation. Note that the premature beat is wide and has a completely different morphology from that of the sinus beat. The fact that the premature beat is not preceded by a P wave and the pause following it is fully compensatory (i.e., the P-P interval containing the PVC equals two sinus cycles) indicates that the sinus mechanism has not been disturbed by the premature beats.

various drugs or stimulants may cause premature ventricular beats.

It is important to distinguish PVCs that are benign from those that are likely to degenerate into more severe dysrhythmias. The former usually disappear during the tachycardia of exercise. If they persist or become more frequent during exercise, the arrhythmia may have greater significance. The following criteria are indications for further investigation of PVCs that could require suppressive therapy: (1) two or more ventricular premature beats in a row, (2) multifocal origin, (3) increased ventricular ectopic activity with exercise, (4) R on T phenomenon (premature ventricular depolarization occurs on the T wave of the preceding beat), and (5) presence of underlying heart disease. The basis of therapy for benign PVCs is reassurance that the arrhythmia is not life threatening. Malignant PVCs are usually secondary to another medical problem, for example, electrolyte imbalance, hypoxia, drug toxicity, cardiac injury, or an intraventricular catheter. Successful treatment includes correction of the underlying abnormality. An intravenous lidocaine bolus and drip is the 1st line of therapy, with more powerful drugs such as amiodarone reserved for refractory cases or for patients with hemodynamic compromise. The choice of a maintenance oral antiarrhythmic agent is determined empirically or during an electrophysiologic study in the catheterization laboratory.

428.2 Supraventricular Tachycardia

Supraventricular tachycardias (SVTs) involve components of the conduction system within or above the bundle of His and can be divided into three major categories: *re-entrant tachycardias using an accessory pathway*, *re-entrant tachycardias without an accessory pathway*, and *ectopic or automatic tachycardias*. Re-entry using an accessory pathway is the most common mechanism of SVT in infants, with an increasing incidence of AV nodal re-entry noted in childhood. The tachycardia is initiated by a premature atrial beat that is most often conducted to the ventricle

through the normal AV nodal pathway (*orthodromic conduction*). The ventricular response finds the AV nodal pathway refractory, but the bypass tract, readily able to conduct in a retrograde fashion, returns to the atrium as an echo beat, which in turn transmits back to the ventricle, and so on (Fig. 428–5). Atrial and junctional ectopic tachycardias are more commonly associated with abnormal hearts (e.g., cardiomyopathy) or with postoperative congenital heart disease.

Figure 428.2-5 Schematic representation of the heart with a right-sided anomalous pathway. The *asterisk* indicates initiation of the sinus beat. The *arrows* indicate the direction and spread of excitation. The electrocardiographic complex shown represents a fusion beat that combines activation over the normal (n) and accessory (a) pathways. The latter inscribes the delta wave. NSR = normal sinus rhythm.

Clinical Manifestations.

Re-entrant SVT is characterized by an abrupt onset and cessation; it may be precipitated by an acute infection and usually occurs when the patient is at rest. Attacks may last only a few seconds or may persist for hours. The heart rate usually exceeds 180 beats/min and may occasionally be as rapid as 300 beats/min (Fig. 428–6). The only complaint may be awareness of the rapid heart rate. Many children tolerate these episodes extremely well, and it is unlikely that short paroxysms are a danger to life. If the rate is exceptionally rapid or if the attack is prolonged, precordial discomfort and heart failure may supervene. SVT may occur in the presence of unoperated congenital heart disease (Ebstein anomaly). In children, SVT may be precipitated by exposure to the sympathomimetic amines contained in over-the-counter decongestants.

In *young infants*, the diagnosis may be more obscure because of the inability to communicate their symptoms. The heart rate at this age is normally rapid, and even in the absence of tachyarrhythmia it increases greatly with crying. Infants with SVT are often initially seen in heart failure because the tachycardia goes unrecognized for a long time. The heart rate during paroxysms is frequently in the range of 200–300 beats/min. If the attack lasts 6–24?hr or more with an extremely fast heart rate, the infant may become acutely ill, have an ashen color, and be restless and irritable. Tachypnea and hepatomegaly are the prominent signs of cardiac failure, and fever and leukocytosis may be present. When tachycardia occurs in the fetus, it can cause severe heart failure and hydrops fetalis.

In *neonates*, SVT is usually manifested as a narrow QRS complex (<0.08?sec). The P wave is visible on a standard electrocardiogram in only 50–60% of neonates with SVT, but it is detectable with a transesophageal lead in most patients. Differentiation from sinus tachycardia may be difficult; if the rate is greater than 230 beats/min with an abnormal P-wave axis (a normal P wave is positive in leads I and aVF), SVT is more likely. The heart rate in SVT also tends to be unvarying, whereas in sinus tachycardia the heart rate varies with changes in vagal and sympathetic tone. Differentiation from ventricular tachycardia is critical because digoxin can precipitate ventricular fibrillation in patients with ventricular tachycardia. The absence of ventricular-to-atrial conduction (and thus only intermittent p waves), the presence of fusion beats, and wide QRS complexes that are dissimilar to the QRS complex during sinus rhythm are diagnostic of ventricular tachycardia.

AV re-entrant tachycardia uses a bypass tract that may either be able to conduct antegrade (Wolff-Parkinson-White [WPW]

Figure 428.2-6 The *upper tracing* shows paroxysmal supraventricular or atrial tachycardia with a ventricular rate of 230/min. The *lower tracing* shows sinus rhythm after DC cardioversion. Note that during the tachycardia the T wave is deformed by an inverted, presumably retrograde P wave. The QRS morphology is unchanged during the tachycardia. The low voltage is due to peripheral edema in a 1-day-old infant who had intrauterine tachycardia and hydrops fetalis.

syndrome) or remain concealed. Patients with WPW syndrome have a small, but real risk of sudden death. If the accessory pathway rapidly conducts in antegrade fashion, the patient is at risk for atrial fibrillation begetting ventricular fibrillation. Risk stratification, including 24?hr Holter monitoring and exercise study, can help differentiate patients at higher risk for sudden death from WPW. Concurrently, any patient with syncope and WPW syndrome should have an electrophysiology study performed.

The typical electrocardiographic features of the **Wolff-Parkinson-White** *syndrome* are usually seen when the patient is not having the tachycardia. These features include a short P-R interval and slow upstroke of the QRS (delta wave) (Fig. 428–7). Though most often present in patients with a normal heart, this syndrome may also be associated with Ebstein anomaly and other congenital heart lesions. The anatomic substrates included in the re-entrant circuit are the AV node and an accessory pre-excitation pathway consisting of a muscular bridge connecting atrium to ventricle on either the right or the left side of the AV ring (see Fig. 428–5). During sinus rhythm, the impulse is carried over both the AV node and the accessory pathway; it produces some degree of fusion of the two depolarization fronts that results in an abnormal QRS. During tachycardia, an impulse is usually carried in anterograde fashion through the AV node (*orthodromic conduction*), which results in a normal QRS complex, and in retrograde fashion through the accessory pathway to the atrium, thereby perpetuating the tachycardia. In these cases, only after cessation of the tachycardia are the typical features of WPW syndrome recognized (see Fig. 428–7). When rapid anterograde conduction occurs through the pre-excitation pathway during tachycardia and the retrograde re-entry pathway to the atrium is via the AV node (*antidromic conduction*), the tachycardiac complexes are wide and the potential for more serious arrhythmias (i.e., ventricular fibrillation) is greater, especially if atrial fibrillation occurs.

AV nodal re-entrant tachycardia involves the use of two pathways within the AV node. This arrhythmia is more commonly seen in adolescence. It is one of the few SVTs that is frequently associated with syncope. This arrhythmia is usually amenable to antiarrhythmic therapy, such as digoxin or propranolol, or to radiofrequency ablation therapy.

Treatment.

Vagal stimulation by submersion of the face in iced saline (in older children) or by placing an ice bag over the face (in infants) may abort the attack. To abolish the paroxysm, older children may be taught **vagotonic maneuvers** such as the

Figure 428.2-7 *A*, Supraventricular tachycardia in a child with Wolff-Parkinson-White (WPW) syndrome. Note the normal QRS complexes during the tachycardia. *B*, Later, the typical features of WPW syndrome are apparent (short P-R interval, delta wave, and wide QRS).

Valsalva maneuver, straining, breath holding, drinking ice water, or adopting a particular posture. When these measures fail, several pharmacologic alternatives are available (see Table 428–1). In stable patients, adenosine by rapid intravenous push is the treatment of choice because of its rapid onset of action and minimal effects on cardiac contractility. Other drugs that have been used for initial treatment of SVT include infusions of phenylephrine (Neo-Synephrine) or edrophonium (Tensilon), which increase vagal tone through the baroreflex, as well as the antiarrhythmic agents quinidine, procainamide, and propranolol. Calcium channel blockers such as verapamil have also been used in the initial treatment of SVT in older children. Verapamil may reduce cardiac output and produce hypotension and cardiac arrest in infants younger than 1 yr; it is therefore contraindicated in this age group. In urgent situations when symptoms of severe heart failure have already occurred, **synchronized DC cardioversion** (0.5–2?W-sec/kg) is recommended as the initial management (Chapter 57.1).

Once the patient has been converted to sinus rhythm, a longer acting agent is selected for maintenance therapy. In patients without an antegrade accessory pathway, digoxin or propranolol is the mainstay of therapy. In children with evidence of pre-excitation (e.g., WPW syndrome), digoxin or calcium channel blockers may increase the rate of anterograde conduction of impulses through the bypass tract and should be avoided. These patients are usually managed in the long term with propranolol. In patients with resistant tachycardias, procainamide, quinidine, flecainide, propafenone, sotalol, and amiodarone have all been used. It should be recognized that most antiarrhythmic agents could have proarrhythmic and negative inotropic effects. Flecainide in particular should be limited to use in patients with otherwise normal hearts.

If cardiac failure occurs because of prolonged tachycardia in an infant with a normal heart, cardiac function usually returns to normal after sinus rhythm is re-instituted, although it may take days to weeks. Infants with SVT diagnosed within the 1st 3–4 mo of life have a lower incidence of recurrence than do those in whom it is initially diagnosed at a later age. These patients have a 40% chance of resolution and are usually treated for a minimum of 1 yr after diagnosis, after which the antiarrhythmic agents can be tapered and the patient watched for signs of recurrence.

Twenty-four hour electrocardiographic (Holter) recordings are useful in monitoring the course of therapy and in detecting brief runs of asymptomatic tachycardia. A brief assessment of arrhythmia control can be made at the bedside with *transesophageal pacing*. More detailed *electrophysiologic studies* performed in the cardiac catheterization laboratory are often indicated in patients with refractory SVTs. During an electrophysiologic study, multiple electrode catheters are placed in different locations in the heart. By comparing the timing of premature beats in different leads, the location of an ectopic focus or bypass tract can be identified. The tachyarrhythmia can be induced by pacing, and different pharmacologic agents can be tested for their ability to inhibit the arrhythmia. These studies are necessary prerequisites to radiofrequency ablation.

Radiofrequency ablation of an accessory pathway is another treatment option commonly used in patients with re-entrant rhythms. It is often used electively in older children and teenagers, as well as for patients in whom multiple agents are required or drug side effects are intolerable or when arrhythmia control is poor. The overall initial success rate ranges from approximately 80 to 95%, depending on the location of the bypass tract or tracts. Surgical ablation of bypass tracts can also be successful in selected patients.

Atrial ectopic tachycardia is an uncommon tachycardia in childhood. It is characterized by a variable rate (seldom greater than 200 beats/min), identifiable P waves with an abnormal axis, and chronicity in either a sustained or intermittent tachycardia.

This form of atrial tachycardia has a single automatic focus rather than the more usual re-entry mechanism. Identification of this mechanism is aided by monitoring the electrocardiogram while initiating vagal or pharmacologic therapy. Re-entry tachycardias “break” suddenly, whereas automatic tachycardias gradually slow down and then gradually speed up again. Atrial ectopic tachycardias are usually more difficult to control pharmacologically than the more common re-entrant tachycardias are. If pharmacologic therapy with a single agent is unsuccessful, catheter ablation is suggested and has a greater than 90% success rate.

Chaotic or multifocal atrial tachycardia is characterized by three or more ectopic P waves with three or more different ectopic P-P cycles, frequent blocked P waves, and varying P-R intervals of conducted beats. This arrhythmia occurs most often in infants younger than 1 yr, usually without cardiac disease, although some evidence suggests an association with viral myocarditis. Drug treatment may not be effective, and multiple agents are often required. Fortunately, when this arrhythmia occurs in infancy, it usually terminates spontaneously by 3 yr of age.

Accelerated junctional ectopic tachycardia (JET) is an automatic (non–re-entry) arrhythmia in which the junctional rate exceeds that of the sinus node and AV dissociation results. This arrhythmia is most often recognized in the early postoperative period after cardiac surgery and may be extremely difficult to control. Reduction of the infusion rate of catecholamines and control of fever are important adjuncts to management. JET in these patients often disappears spontaneously without specific treatment; JET in the absence of surgery carries a more guarded prognosis. Junctional tachycardia may also be a sign of digitalis intoxication; when intoxication occurs, the drug should be discontinued. Intravenous amiodarone is effective in the treatment of postoperative JET. Patients who require chronic therapy may respond to amiodarone or sotalol.

Atrial flutter, also known as *intra-atrial re-entrant tachycardia*, is a regular or

regularly irregular tachycardia characterized by atrial activity at a rate of 250–400 beats/min. These contractions are thought to be due to a re-entrant or circus rhythm originating in the atria and involving a micro–re-entrant loop within the atrial tissue and some form of anatomic obstacle that creates a discontinuity in conduction (fibrosis, surgical suture site, valve annulus). Because the AV node cannot transmit such rapid impulses, some degree of AV block is virtually always present, and the ventricles respond to every 2nd–4th atrial beat. Occasionally, the response is variable and the rhythm appears irregular.

In older children, atrial flutter usually occurs in the setting of congenital heart disease; however, neonates with atrial flutter frequently have normal hearts. Atrial flutter may occur during acute infectious illnesses but is most often seen in patients with large stretched atria, such as those associated with long-standing mitral or tricuspid insufficiency, tricuspid atresia, Ebstein anomaly, or rheumatic mitral stenosis. Atrial flutter can also occur after palliative or corrective intra-atrial surgery. Uncontrolled atrial flutter may precipitate heart failure. Vagal maneuvers (such as carotid sinus pressure or iced saline submersion) or adenosine generally produce a temporary slowing of the heart rate. The diagnosis is confirmed by electrocardiography, which demonstrates the rapid and regular atrial saw-toothed flutter waves. Atrial flutter usually converts immediately to sinus rhythm by synchronized DC cardioversion, which is most often the treatment of choice. Patients with chronic atrial flutter in the setting of congenital heart disease may be at increased risk for thromboembolism and stroke and should thus undergo anticoagulation before elective cardioversion. Digitalis slows the ventricular response in atrial flutter by prolonging conduction time through the AV node. After digitalization, a type I agent such as quinidine or procainamide is usually needed to maintain adequate control. Type III agents such as amiodarone and sotalol have shown promise and may be useful in patients refractory to type I agents. Other modalities, including radiofrequency and surgical ablation, have been used in older patients with congenital heart disease with moderate success. Neonates with normal hearts who respond to digoxin may be treated for 6–12 mo, after which the medication can often be discontinued.

Atrial fibrillation is much less common in children and rare in infants. The atrial excitation is chaotic and more rapid (300–700 beats/min) and produces an irregularly irregular ventricular response and pulse (Fig. 428–8). This rhythm disorder is most often the result of a chronically stretched atrial myocardium. Atrial fibrillation occurs most frequently in older children with rheumatic mitral valve disease. It is also seen rarely as a complication of intra-atrial surgery, in patients with left atrial enlargement secondary to left AV valve insufficiency, in conditions producing atrial flutter, and in patients with WPW syndrome. Thyrotoxicosis, pulmonary emboli, and pericarditis should be suspected in a previously normal older child or adolescent with atrial fibrillation. Atrial fibrillation may be familial. The best initial treatment is digitalization, which restores the ventricular rate to normal, although the atrial fibrillation usually persists. Digoxin is not given if WPW syndrome is present. Normal sinus rhythm may then be restored with a type I agent such as quinidine or procainamide or by DC cardioversion. Patients with chronic atrial fibrillation are at risk for the development of thromboemboli and stroke and should undergo anticoagulation with warfarin. Patients being treated by elective cardioversion should also undergo anticoagulation.

428.3 Ventricular Tachyarrhythmias

Ventricular tachycardia (VT) is less common than SVT in pediatric patients. VT is defined as at least three PVCs at greater than 120 beats/min. It may be paroxysmal or incessant. VT may be associated with myocarditis, anomalous origin of a coronary artery, arrhythmogenic right ventricular dysplasia, mitral valve prolapse, primary cardiac tumors, cardiomyopathy, prolonged Q-T interval of either congenital or acquired (proarrhythmic drugs) cause, WPW syndrome, or drugs (cocaine, amphetamines); it may develop many years after intraventricular surgery (tetralogy of Fallot, ventricular septal defect) or occur without obvious organic heart disease. VT must be distinguished from SVT with aberrancy or rapid conduction over an accessory pathway (Table 428–2). The presence of capture and fusion

Figure 428.3-8 Atrial fibrillation, characterized by the absence of P waves; presence of fibrillatory waves, which are grossly irregular, rapid undulations; and an irregular ventricular response. Fibrillatory waves may not be visible in all leads and should be carefully sought in every tracing with irregular R-R intervals. (The coexisting qR in V_1 is diagnostic of right ventricular hypertrophy in this patient with Eisenmenger syndrome.)

TABLE 428.3-2 -- Diagnosis of Tachyarrhythmias

	Electrocardiographic Findings			
	Heart Rate (Beats/min)	***P Wave***	***QRS Duration***	***Regularity***
Sinus tachycardia	<225	Always present	Normal	Rate varies with respiration
		Normal axis		
Atrial tachycardia	180–320	Present—50%	Normal or prolonged (RBBB pattern)	Regular
		Superior axis common		
Atrial fibrillation	120–180	Fibrillatory waves	Normal or prolonged (RBBB pattern)	Irregularly irregular

Atrial flutter	Atrial: 250–400	Saw-toothed flutter waves	Normal or prolonged (RBBB pattern)	Regular ventricular response (e.g., 2:1, 3:1, 3:2, and so on)
	Ventricular response variable: 100–320			
Ventricular tachycardia	120–240	Absent or atrioventricular dissociation	Usually prolonged	Slightly irregular
RBBB = right bundle branch block.				

beats helps confirm the diagnosis. Although some children tolerate rapid ventricular rates for many hours, this arrhythmia should be promptly treated because hypotension and degeneration into ventricular fibrillation may result. For patients who are hemodynamically stable, intravenous lidocaine is the initial drug of choice. If treatment is to be successful, it is critical to search for and correct any underlying abnormalities such as electrolyte imbalance, hypoxia, or drug toxicity. Alternative drugs include amiodarone, procainamide, and propranolol (see Table 428–1). Amiodarone is quite useful during cardiac arrest (Chapter 57.1). Overdrive ventricular pacing may also be effective, although it may occasionally cause the arrhythmia to deteriorate into ventricular fibrillation. In the neonatal period, ventricular tachycardia may be associated with an anomalous left coronary artery (see Chapter 425.2) or a myocardial tumor.

Unless a clearly reversible cause is identified, electrophysiologic study is usually indicated for patients in whom VT has developed.

Ventricular fibrillation is a chaotic dysrhythmia that results in death unless an effective ventricular beat is rapidly re-established. A thump on the chest sometimes restores sinus rhythm. Usually, external cardiac massage with artificial ventilation and DC defibrillation is necessary. If defibrillation is ineffective or fibrillation recurs, amiodarone may be given intravenously and defibrillation repeated. After recovery from ventricular fibrillation, a search should be made for the underlying cause. The Q-T interval should be measured to rule out long Q-T syndrome (LQTS). Electrophysiologic study is usually indicated for patients in whom ventricular fibrillation has developed unless a clearly reversible cause is identified. If WPW syndrome is noted, ablation should be performed. For patients in whom no correctable abnormality can be found, an ICD should be strongly considered because of the high risk of sudden death.

428.4 Long Q-T Syndrome

A particularly malignant form of ventricular arrhythmia called torsades de pointes occurs in patients with LQTS; it is a cause of syncope and sudden death and may be associated with sudden infant death syndrome or drowning. About 50% of cases are familial: **Romano-Ward syndrome** (RWS) is a common form of LQTS that exhibits autosomal dominant transmission with low penetrance, but some cases are autosomal recessive; **Jervell-Lange-Nielsen syndrome** (JLNS) is an uncommon form of LQTS, has autosomal recessive transmission, and may be associated with congenital deafness. The remainder of cases are sporadic. Genetic studies have identified mutations in cardiac potassium and sodium channels. In LQT1, a form of RWS, the gene is on chromosome 11p15.5 and encodes a potassium channel (KVLQT1). *LQT2* gene is on chromosome 7q35-36, which encodes HERG (human ether a go-go related gene), a potassium channel. *LQT3* is a defect on chromosome 3p21-24 and encodes a sodium channel (SCN5A). The cause of *LQT4* is unknown. *LQT5* is a mutation on chromosome 21q22.1 and encodes a regulator (minK) of potassium channels. *LQT6* is on chromosome 21q22.1 and is a minK-related peptide. At least one form of JLNS is due to homozygous mutations of *KVLQT1*, whereas the heterozygous state is manifested as RWJ. Genotype may predict clinical manifestations; for example, LQT1 events are stress induced whereas events in LQT3 occur during sleep. LQT2 events have an intermediate pattern. LQT3 has the highest probability for sudden death, followed by LQT2 and then LQT1. Drugs may prolong the Q-T interval directly (terfenadine, astemizole) or more often when drugs such as erythromycin or ketoconazole inhibit their metabolism.

The clinical manifestation of LQTS in children is most often a syncopal episode often brought on by exercise, fright, or a sudden startle; some events occur during sleep. Patients can initially be seen with seizures, presyncope, and palpitations, and about 10% are initially in cardiac arrest. The diagnosis is based on electrocardiographic and clinical criteria. Not all patients with long Q-T intervals have LQTS, and rare patients with normal Q-T intervals on a resting electrocardiogram may have LQTS. A heart rate–corrected Q-T interval of greater than 0.47?sec is highly indicative, whereas a Q-T interval of greater than 0.44?sec is suggestive. Other features include notched T waves, T wave alternans, a low heart rate for age, a history of syncope (especially with stress), and a familial history of either LQTS or unexplained sudden death. Twenty-four hour Holter monitoring and exercise testing are adjuncts to the diagnosis.

Treatment of LQTS includes the use of ß-blocking agents at doses that blunt the heart rate response to exercise. Some patients may require a pacemaker because of drug-induced profound bradycardia. In patients with continued syncope despite treatment and for those who have experienced cardiac arrest, many authorities recommend an ICD.

428.5 Bradyarrhythmias

Sinus arrest and *sinoatrial block* may cause a sudden pause in the heartbeat. The former is presumably caused by failure of impulse formation within the sinus node and the latter by a block between the sinus impulse and the surrounding atrium. These arrhythmias are rare in childhood except as manifestations of digitalis intoxication or in patients who have had extensive atrial surgery.

AV block may be divided into three forms. In **1st-degree block**, the P-R interval is prolonged, but all the atrial impulses

are conducted to the ventricle. In **2nd-degree block**, some impulses are not conducted to the ventricle. In one variant of 2nd-degree block known as the **Wenckebach type** (also called *Mobitz type I*), the P-P interval remains constant and the P-R interval increases progressively until a P wave is not conducted. In the cycle following the dropped beat, the P-R interval is again shorter (Fig. 428–9). In *Mobitz type II*, occasional atrial beats are not conducted to the ventricle; this conduction defect has more potential to cause syncope and may be progressive. In **3rd-degree block** (complete heart block), no impulses from the atria reach the ventricles.

Congenital complete AV block in children is most often caused by autoimmune injury of the fetal conduction system by maternally derived IgG antibodies (anti-SSA/Ro, anti-SSB/La) in a mother with overt or, more often, asymptomatic SLE. Rheumatoid arthritis, dermatomyositis, or Sjögren syndrome is rarely the primary autoimmune process. Autoimmune disease accounts for 60–70% of all cases of congenital complete heart block and about 80% of cases in which the heart is structurally normal. Complete heart block is also seen in patients with complex congenital heart disease, abnormal embryonic development of the conduction system, myocardial tumors, myocarditis, myocardial abscess secondary to endocarditis, LQTS, postsurgical repair of congenital heart disease involving the ventricular septum, and Kearns-Sayre syndrome. The incidence of congenital complete heart block is 1 in 20,000–25,000 live births; a high fetal wastage rate may cause an underestimation of its true incidence, however. In some infants of mothers with SLE, complete heart block is not present at birth but develops within the 1st 3–6 mo after birth. Steroids may be helpful in preventing the development of complete heart block. The arrhythmia is occasionally suspected in the fetus and may produce hydrops fetalis. The dissociation between atrial and ventricular contractions can be diagnosed by fetal echocardiography. Infants with associated congenital heart disease who experience heart failure in the 1st wk of life are at greatest risk for serious illness.

In older children with otherwise normal hearts, the condition is commonly asymptomatic, although syncope may occur. Older infants may have night terrors, tiredness with frequent naps, and irritability. The peripheral pulse is prominent as a result of the compensatory large ventricular stroke volume and peripheral vasodilation; systolic blood pressure is elevated. Jugular venous pulsations occur irregularly and may be large when the atrium contracts against a closed tricuspid valve (cannon wave). Exercise and atropine may produce an acceleration of 10–20 beats/min or more. Systolic murmurs are frequently audible along the left sternal border, and apical mid-diastolic murmurs are not unusual. Heart block results in enlargement of the heart on the basis of increased diastolic ventricular filling.

The *diagnosis* is confirmed by electrocardiography; the P waves and QRS complexes have no constant relationship (Fig. 428–10).

Figure 428.5-9 Wenckebach phenomenon (Mobitz I). The P-R interval gradually lengthens until the 4th P wave in the cycle is not conducted to the ventricle (*arrow*). The ensuing P-R interval is once again normal.

Figure 428.5-10 Complete atrioventricular (AV) block. The ventricular rate is regular at 53/min. The atrial rate varied from 65 to 95/min. The QRS morphology is normal, which is usual in congenital AV block.

The QRS duration may be prolonged, or it may be normal if the heartbeat is initiated high in the bundle of His.

The *prognosis* for congenital complete heart block is usually favorable; patients who have been observed to the age of 30–40 yr have lived normal, active lives. Some patients have episodes of dizziness with or without syncope (**Stokes-Adams attacks**); this symptom requires the implantation of a permanent cardiac pacemaker. Pacemaker implantation should be considered for patients in whom symptoms develop, such as progressive cardiac enlargement, prolonged pauses, or awake heart rates of 40 beats/min or less.

Cardiac pacing is required in neonates with ventricular rates of 50 beats/min or less who show evidence of hydrops or experience heart failure after birth. Isoproterenol, atropine, or epinephrine may be used to try to increase the heart rate temporarily until pacemaker placement can be arranged. Patients with complete heart block and congenital heart disease should also receive a pacemaker. Transthoracic epicardial pacemaker implants have traditionally been used in infants; transvenous placement of pacemaker leads is available for older infants and young children.

Postsurgical complete AV block can occur after any open heart procedure requiring suturing near the AV valves or crest of the ventricular septum. Because postoperative heart block may be transient, the patient should be maintained with temporary pacing wires inserted at the time of surgery until at least 10–14 days, after which it is much less likely that sinus rhythm will return.

428.6 Sick Sinus Syndrome

Sick sinus syndrome is the result of abnormalities in the sinus node or atrial conduction pathways, or both. This syndrome may occur in the absence of congenital heart disease and has been reported in siblings, but it is most commonly seen after surgical correction of congenital heart defects, especially the atrial switch (Mustard or Senning) operation for transposition of the great arteries. *Clinical manifestations* depend on the heart rate. Most patients remain asymptomatic without treatment, but dizziness and syncope can occur during periods of marked sinus slowing with failure of junctional escape (Fig. 428–11). SVT may alternate with bradycardia (*bradycardia-tachycardia syndrome*) and cause palpitations, exercise intolerance, or dizziness. Treatment must be individualized. Drug therapy to control tachyarrhythmias (e.g., propranolol, quinidine, procainamide) may suppress sinus and AV node function to such a degree that symptomatic bradycardia may be produced. Therefore, insertion of a demand ventricular pacemaker in conjunction with drug therapy is usually necessary for symptomatic patients.

428.7 Sudden Death

Sudden death other than sudden infant death syndrome (see Chapter 360) is rare in children younger than 18 yr. Potential causes are noted in Box 428–1 . Competitive high-school sports

Figure 428.7-11 Sick sinus syndrome with bradytachycardia. Note the bursts of supraventricular tachycardia, probably multifocal in origin, followed by long periods of sinus arrest and by sinus bradycardia.

(basketball, football) are high-risk environmental factors. Approximately 65% of sudden deaths are due to heart-related problems in patients with normal or congenitally (corrected, palliated, or unoperated) abnormal hearts. Symptoms may be absent before the event but, if present, include syncope, chest pain, dyspnea, and palpitations. Patients may have a family history

Box 428.7-1. Potential Causes of Sudden Death in Infants, Children, and Adolescents

SIDS AND SIDS "MIMICS"

- SIDS
- Long Q-T syndromes
- Inborn errors of metabolism
- Child abuse
- Myocarditis
- Duct-dependent congenital heart disease

CORRECTED OR UNOPERATED CONGENITAL HEART DISEASE

- Aortic stenosis
- Tetralogy of Fallot

Anorexia nervosa

Electrolyte disturbances

SIDS = sudden infant death syndrome.

(dilated or hypertrophic cardiomyopathy, long Q-T interval, right ventricular dysplasia, mitral valve prolapse, Marfan syndrome) of heart disease or sudden death. Death often follows exertion or exercise.

Commotio cordis is a nearly universally fatal condition that follows blunt nonpenetrating trauma to the chest (e.g., from a baseball or hockey puck). Occasionally innocent-appearing chest blows while at home or at a playground may be fatal. Patients experience immediate ventricular fibrillation in the absence of identifiable cardiac trauma (contusion, hematoma, lacerated coronary artery). Death results from ventricular fibrillation that is unresponsive to all resuscitative efforts in 85–90% of children.

Prevention of Sudden Death.

Many of the more common causes of sudden death in children and adolescents can be identified from the patient's history (prodromal symptoms), the family history, and physical examination.

Avoiding high-risk behavior (cocaine, anorexia nervosa) and knowledge of drug side effects (tricyclic antidepressants) or drug interactions (terfenadine [Seldane]-erythromycin) is critical. Chest-protecting equipment and softer baseballs may prevent *commotio cordis*. Prompt cardiopulmonary resuscitation *and* rapid defibrillation by an automatic external defibrillator or by an emergency medical services rescue team improves survival.

In patients with known risk factors for sudden death, ICD therapy may be used as a protective measure.

Chapter 429 - Infective Endocarditis

Infective endocarditis includes acute and subacute bacterial endocarditis, as well as nonbacterial endocarditis caused by viruses, fungi, and other microbiologic agents. It is a significant cause of morbidity and mortality in children and adolescents despite advances in the management and prophylaxis of the disease with antimicrobial agents. The inability to eradicate infective endocarditis by prevention or early treatment stems from several factors: the nature of the infecting organism has changed; physicians, dentists, and the public are not sufficiently aware of the threat of infective endocarditis and the preventive measures available; diagnosis may be difficult when delayed; and special risk groups have emerged, including an increasing number of intravenous drug users, survivors of cardiac surgery, patients taking immunosuppressant medications, and patients who require chronic intravascular catheters. In addition, many patients get endocarditis on what was thought to be a previously healthy native valve. Furthermore, endocarditis from oral flora may occur without a preceding dental procedure.

Etiology.

Viridans-type streptococci (a-hemolytic streptococci) and *Staphylococcus aureus* are the leading causative agents responsible for endocarditis in pediatric patients. Other organisms cause endocarditis less frequently, and in approximately 6% of cases, blood cultures are negative for any organisms (Box 429–1). No relationship exists between the infecting organism and the type of congenital defect, the duration of illness, or the age of the child. Staphylococcal endocarditis is more common in patients with no underlying heart disease; viridans group streptococcal infection is more common after dental procedures, group D enterococci are seen more often after lower bowel or genitourinary manipulation, *Pseudomonas aeruginosa* or *Serratia marcescens* is seen more frequently in intravenous drug users, and fungal organisms are encountered after open heart surgery. Coagulase-negative staphylococci are common in the presence of an indwelling central venous catheter.

Epidemiology.

Infective endocarditis is often a complication of congenital or rheumatic heart disease but can also occur in children without any abnormal valves or cardiac malformations. In developed countries, congenital heart disease is the overwhelming predisposing factor. Endocarditis is rare in infancy; in this age group it usually follows open heart surgery or is associated with a central venous line.

Patients with congenital heart lesions in which blood is ejected at high velocity through a hole or stenotic orifice are most susceptible to endocarditis. Vegetations usually form at the site of the endocardial or intimal erosion that results from the turbulent flow. Children with ventricular septal defects (VSDs), left-sided valvular disease, and systemic-pulmonary arterial communications (including palliative shunts) are at highest risk. Tetralogy of Fallot, VSD, aortic stenosis, patent ductus arteriosus, transposition of the great arteries, and Blalock-Taussig shunts are the most frequent structural lesions associated with endocarditis. In older patients, congenital bicuspid aortic valves and mitral valve prolapse pose additional risks for endocarditis. Surgical correction of congenital heart disease may reduce, but does not eliminate the risk of endocarditis, with the exception of repair of a simple atrial septal defect or patent ductus arteriosus. Children who have undergone valve replacement or valved conduit repair are at particularly high risk.

Box 429-1. Bacterial Agents in Pediatric Infective Endocarditis

COMMON: NATIVE VALVE OR OTHER CARDIAC LESIONS

Viridans group streptococci (*S. mutans, S. sanguis, S. mitis*)

Staphylococcus aureus

Group D streptococcus (enterococcus) (*S. bovis, S. faecalis*)

UNCOMMON: NATIVE VALVE OR OTHER CARDIAC LESIONS

Viridans group streptococcus

Pseudomonas aeruginosa

Serratia marcescens

Diphtheroids

Legionella species[*]

HACEK group[†]

Fungi[‡]

*These fastidious bacteria plus some fungi may produce culture-negative endocarditis. Detection may require special media, incubation for more than 7 days, or serologic tests.
† The HACEK group includes *Haemophilus* species (*H. paraphrophilus, H. parainfluenzae, H. aphrophilus), Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella species.*
‡ *Candida species, Aspergillus species, Pseudallescheria boydii, Histoplasma capsulatum.*

In approximately 30% of patients with infective endocarditis, a predisposing factor is recognized. A surgical or dental procedure can be implicated in approximately 65% of cases in which the potential source of bacteremia is identified. Poor dental hygiene in children with cyanotic heart disease results in a greater risk for endocarditis. The occurrence of endocarditis directly after heart surgery is relatively low, but it is frequently an antecedent event.

Clinical Manifestations (**Box 429–2** **).**

Early manifestations are usually mild, especially when viridans group streptococci are the infecting organisms. Prolonged fever without other manifestations (except occasionally weight loss) that persists for as long as several months may be the only symptom. Alternatively, the onset may be acute and severe, with high, intermittent fever and prostration. Usually, the onset and course vary between these two

extremes. The symptoms are often nonspecific and consist of low-grade fever with afternoon elevations, fatigue, myalgia, arthralgia, headache, and at times, chills, nausea, and vomiting. New or changing heart murmurs are common, particularly with associated heart failure. Splenomegaly and petechiae are relatively common. Serious neurologic complications such as embolic strokes, cerebral abscesses, mycotic aneurysms, and hemorrhage are most often associated with staphylococcal disease and may be late manifestations. Meningismus, increased intracranial pressure, altered sensorium, and focal neurologic signs are manifestations of these complications. Myocardial abscesses may

Renal failure: azotemia, high creatinine (glomerulonephritis)

Chest radiograph: bilateral infiltrates, nodules, pleural effusions

Echocardiographic evidence of valve vegetations, prosthetic valve dysfunction or leak, myocardial abscess, new-onset valve insufficiency

CNS = central nervous system.

occur with staphylococcal disease and may rupture into the pericardium and produce purulent pericarditis. Pulmonary and other systemic emboli are infrequent, except with fungal disease. Many of the classic skin findings develop late in the course of the disease; they are seldom seen in appropriately treated patients. Such manifestations include *Osler nodes* (tender, pea-sized intradermal nodules in the pads of the fingers and toes), *Janeway lesions* (painless small erythematous or hemorrhagic lesions on the palms and soles), and *splinter hemorrhages* (linear lesions beneath the nails). These lesions may represent vasculitis produced by circulating antigen-antibody complexes.

Identification of infective endocarditis is most often based on a high index of suspicion during evaluation of an infection in a child with an underlying contributory factor.

Diagnosis.

The critical information for appropriate treatment of infective endocarditis is obtained from blood cultures. All other

laboratory data are secondary in importance (see Box 429–2). Blood specimens for culture should be obtained as promptly as possible, even if the child feels well and has no other physical findings. Three to five separate blood collections should be obtained after careful preparation of the phlebotomy site. Contamination presents a special problem inasmuch as bacteria found on the skin may themselves cause infective endocarditis. The timing of collections is not important because bacteremia can be expected to be relatively constant. In 90% of cases of endocarditis, the causative agent is recovered from the 1st two blood cultures. The laboratory should be notified that endocarditis is suspected so that if necessary, the blood can be cultured on enriched media for longer than usual (>7 days) to detect nutritionally deficient and fastidious bacteria or fungi. Antimicrobial pretreatment of the patient reduces the yield of blood cultures to 50–60%. The microbiology laboratory should be notified if the patient has received antibiotics so that more sophisticated methods can be used to recover the offending agent. Other specimens that may be cultured include scrapings from cutaneous lesions, urine, synovial fluid, abscesses, and in the presence of manifestations of meningitis, cerebrospinal fluid. Serologic diagnosis is necessary in patients with unusual or fastidious microorganisms (see Box 429–1).

The index of suspicion should be high when evaluating infection in a child with an underlying contributing factor. The combination of M-mode, two-dimensional, and transesophageal echocardiography enhances the ability to diagnose endocarditis. M-mode echocardiography can detect valvular vegetations larger than 2–3?mm. Two-dimensional echocardiography can identify the size, shape, location, and mobility of the lesion; when combined with Doppler studies, the presence of valve dysfunction (regurgitation, obstruction) can be determined and its effect on left ventricular performance quantified. Echocardiography may also be helpful in predicting embolic complications given that lesions greater than 1?cm and fungating masses are at greatest risk for embolization. The absence of vegetations does not exclude endocarditis, and vegetations are often not visualized in the early phases of the disease or in patients with complex congenital heart lesions.

The Duke criteria help in the diagnosis of endocarditis. Major criteria include (1) positive blood cultures (two separate cultures for a usual pathogen, two or more for less typical pathogens) and (2) evidence of endocarditis on echocardiography (intracardiac mass on a valve or other site, regurgitant flow near a prosthesis, abscess, partial dehiscence of prosthetic valves, or new valve regurgitant flow). Minor criteria include predisposing conditions, fever, embolic-vascular signs, immune complex phenomena (glomerulonephritis, arthritis, rheumatoid factor, Osler nodes, Roth spots), a single positive blood culture or serologic evidence of infection, and echocardiographic signs not meeting the major criteria. Two major criteria, one major and three minor, or five minor criteria suggest definite endocarditis.

Prognosis and Complications.

In the pre-antibiotic era, infective endocarditis was a fatal disease. Despite the use of antibiotic agents, mortality remains at 20–25%. Serious morbidity occurs in 50–60% of children with documented infective endocarditis; the most common is heart failure caused by vegetations involving the aortic or mitral valve. Myocardial abscesses and toxic myocarditis may also lead to heart failure without characteristic changes in auscultatory findings. Systemic emboli, often with central nervous system manifestations, are a major threat. Pulmonary emboli may occur in children with VSD or the tetralogy of Fallot, although massive life-threatening pulmonary embolization is rare. Other complications include mycotic aneurysms, rupture of a sinus of Valsalva, obstruction of a valve secondary to large vegetations, acquired VSD, and heart block as a result of involvement (abscess) of the conduction system. Additional complications include meningitis, osteomyelitis, arthritis, renal abscess, and immune

complex–mediated glomerulonephritis.

Treatment.

Antibiotic therapy should be instituted immediately once a definitive diagnosis is made. When virulent organisms are responsible, small delays may result in progressive endocardial damage and are associated with a greater likelihood of severe complications. The choice of antibiotics, method of administration, and length of treatment are outlined in Table 429–1 . High serum bactericidal levels must be maintained long enough to eradicate organisms that are growing in relatively inaccessible avascular vegetations. Between 5 and 20 times the minimal in vitro inhibiting concentration must be produced at the site of infection to destroy bacteria growing at the core of these lesions. Several weeks is required for a vegetation to organize completely; therapy must be continued through this period so that recrudescence can be avoided. A total of 4–6 wk of treatment is recommended, with serumcidal levels by tube dilution of at least 1:8 after a dose of antibiotic. Depending on the clinical and laboratory responses, antibiotic therapy may require modification, and in some instances more prolonged treatment is required. With highly sensitive viridans group streptococcal infections, shortened regimens that include oral penicillin for some portion have been recommended. In nonstaphylococcal disease, bacteremia usually resolves in 24–48?hr, whereas fever resolves in 5–6 days with appropriate antibiotic therapy. Resolution with staphylococcal disease takes longer.

Digitalis, salt restriction, and diuretic therapy should be used for the treatment of heart failure. Surgical intervention for infective endocarditis is indicated for severe aortic or mitral valve involvement with intractable heart failure. Rarely, a mycotic aneurysm, rupture of an aortic sinus, or dehiscence of an intracardiac patch requires an emergency operation. Other surgical indications include failure to sterilize the blood despite adequate antibiotic levels, myocardial abscess, recurrent emboli, and increasing size of vegetations while receiving therapy. Although antibiotic therapy should be administered for as long as possible before surgical intervention, active infection is not a contraindication if the patient is critically ill as a result of severe hemodynamic deterioration from infective endocarditis. Removal of vegetations and, in some instances, valve replacement may be lifesaving, and sustained antibiotic administration will most often prevent re-infection. Replacement of infected prosthetic valves carries a higher risk.

Fungal endocarditis is difficult to manage and has a poor prognosis regardless of treatment. It has been encountered after cardiac surgery, especially in severely debilitated or immunosuppressed patients. The drugs of choice are amphotericin B and 5-fluorocytosine. Surgery to excise infected tissue is occasionally attempted, though often with limited success.

Prevention.

Antimicrobial prophylaxis before various procedures, including dental cleaning and other forms of dental manipulation, reduces the incidence of infective endocarditis in susceptible patients (Tables 429–2 and 429–3). Continuing education regarding prophylaxis is important, especially in teenagers and young adults, who often have poor knowledge of their own congenital heart lesion. Proper general dental care and oral hygiene are most important in decreasing the risk of infective endocarditis in susceptible individuals. Vigorous treatment of sepsis and local infections and careful asepsis during heart surgery and catheterization reduce the incidence of infective endocarditis.

TABLE 429-1 -- Treatment of Infective Endocarditis

Etiologic Agent	Drug	Dose	Route
Streptococcus viridans, Streptococcus bovis (minimal inhibitory concentration [MIC]=0.1?µg/mL	(1) Penicillin G *or*	200,000–300,000?U/kg/24?hr q4h, not to exceed 20 million U/24?hr	IV

	Vancomycin	As above No. 5	IV
	plus gentamicin	As above No. 2	IV
	plus optional ampicillin	As above No. 4	IV

IV = intravenous; PO = oral.

**Add gentamicin for relatively resistant organisms. Monitor vancomycin peaks 1?hr after infusion (30–45?µ g/mL). Adjust the dose according to vancomycin levels.*
†Desensitization should be considered for patients who are allergic to penicillin. Cephalosporins are not recommended.
‡May require valve (device) replacement.

TABLE 429-2 -- **Recommendations of the American Heart Association for Prophylaxis Against Bacterial Endocarditis**

Dental and Oral Procedures or Surgery of the Upper Respiratory Tract or Esophagus		**Gastrointestinal and Genitourinary Tract Surgery and Instrumentation**	
For most patients	Oral amoxicillin Adults, 2.0?g, children, 50?mg/kg 1 hr before procedure	High-risk patients	IM or IV ampicillin Adults, 2.0?g, children, 50?mg/kg *plus*
For patients unable to take oral medication	IM or IV ampicillin Adults, 2.0?g, children, 50?mg/kg given within 30?min before procedure		IM or IV gentamicin 1.5?mg/kg (maximal dose, 120?mg) given within 30?min before procedure *plus 6 hr later*
Ampicillin- and amoxicillin-allergic patients	Oral clindamycin Adults, 600?mg, children, 20?mg/kg 1 hr before procedure *or*		IM or IV ampicillin or oral amoxicillin Adults, 1?g, children, 25?mg/kg
	Oral cephalexin* or cefadroxil* Adults, 2.0?g, children, 50?mg/kg 1 hr before procedure *or* Oral azithromycin *or*clarithromycin Adults, 500?mg, children, 15?mg/kg 1 hr before procedure	High-risk patients allergic to ampicillin and amoxicillin	IV vancomycin Adults, 1.0?g, children, 20?mg/kg given over 1–2 hr *plus* IM or IV gentamicin 1.5?mg/kg (maximal dose, 120?mg); complete injection/infusion within 30?min before starting procedure
Ampicillin- and amoxicillin-allergic patients unable to take oral medications	IV clindamycin Adults, 600?mg, children, 20?mg/kg given within 30?min before procedure *or* IV cefazolin	Moderate-risk patients	Oral amoxicillin Adults, 2.0?g, children, 50?mg/kg 1 hr before procedure *or* IM or IV ampicillin Adults, 2.0?g, children, 50?mg/kg given within 30?min before procedure

	Adults, 1.0?g, children, 25?mg/kg given within 30?min before procedure	Moderate-risk patients who are allergic to ampicillin and amoxicillin	IV vancomycin Adults, 1.0?g, children, 20?mg/kg given over 1–2 hr; complete infusion within 30?min of starting procedure
High-risk patients: *prosthetic heart valves (including homografts), previous endocarditis, complex cyanotic congenital heart disease (e.g., transposition of great vessels, tetralogy of Fallot, single ventricle), systemic-to-pulmonary artery shunts or conduits.*			
Moderate-risk patients: *most other congenital heart diseases (other than those specifically listed previously or further on), acquired valve dysfunction (e.g., rheumatic heart disease), hypertrophic cardiomyopathy.*			
Negligible-risk patients *(prophylaxis not recommended): isolated secundum ASD; surgical repair of ASD, VSD, or PDA (without residua and beyond 6 mo after repair); previous coronary artery bypass surgery; functional heart murmurs; previous Kawasaki disease or rheumatic fever without valve dysfunction; cardiac pacemakers; implantable defibrillators.*			
The risk for mitral valve prolapse is controversial. The latest American Heart Association recommendations categorize mitral valve prolapse with regurgitation or thickened leaflets, or both, as a moderate risk; mitral valve prolapse without regurgitation is categorized as negligible risk (for further details see the reference).			
IM = intramuscularly; IV = intravenously; ASD = atrial septal defect; VSD = ventricular septal defect; PDA = patent ductus arteriosus.			
Adapted from Dajani AS, Taubert KA, Wilson W, et al: Prevention of bacterial endocarditis. Recommendations by the American Heart Association. JAMA 1997; 277:1794.			

**Cephalosporins should not be used in patients with an immediate-type hypersensitivity reaction to penicillins.*

Chapter 430 - Rheumatic Heart Disease

Rheumatic involvement of the valves and endocardium is the most important manifestation of rheumatic fever (see Chapter 147). The valvular lesions begin as small verrucae composed of fibrin and blood cells along the borders of one or more of the heart valves. The mitral valve is affected most often, followed in frequency by the aortic valve; right-sided heart manifestations are rare. As the inflammation subsides, the verrucae tend to disappear and leave scar tissue. With repeated attacks of rheumatic fever, new verrucae form near the previous ones, and the mural endocardium and chordae tendineae become involved.

PATTERNS OF VALVULAR DISEASE

Mitral Insufficiency

Pathophysiology.

Mitral insufficiency is the result of structural changes that usually include some loss of valvular substance and shortening and thickening of the chordae tendineae. During acute rheumatic fever with severe cardiac involvement, heart failure is caused by a combination of mitral insufficiency coupled with inflammatory disease of the pericardium, myocardium, endocardium, and epicardium. Because of the high volume load and inflammatory process, the left ventricle becomes enlarged. The left atrium dilates as blood regurgitates into this chamber. Increased left atrial pressure results in pulmonary congestion and symptoms of left-sided heart failure. Spontaneous improvement usually occurs with time, even in patients in whom mitral insufficiency is severe at the onset. The resultant chronic lesion is most often mild or moderate in severity, and the patient is asymptomatic. More than half of patients with acute mitral insufficiency no longer have the mitral murmur 1 yr later. In patients with severe chronic mitral insufficiency, pulmonary arterial pressure becomes elevated, the right ventricle and atrium become enlarged, and right-sided heart failure subsequently develops.

Clinical Manifestations.

The physical signs of mitral insufficiency depend on its severity. With mild disease, signs of heart failure are not present, the precordium is quiet, and auscultation reveals a high-pitched holosystolic murmur at the apex that radiates to the axilla. With severe mitral insufficiency, signs of chronic heart failure may be noted. The heart is enlarged, with a heaving apical left ventricular impulse and often an apical systolic thrill. The 2nd heart sound may be accentuated if pulmonary hypertension is present. A 3rd heart sound is generally prominent. A holosystolic murmur is heard at the apex with radiation to the axilla. A short mid-diastolic rumbling murmur is caused by increased blood flow across the mitral valve as a result of the insufficiency. Auscultation of a diastolic murmur does not necessarily mean that mitral stenosis is present. The latter lesion takes many years to develop and is characterized by a diastolic murmur of greater length with presystolic accentuation.

The electrocardiogram and roentgenograms are normal if the lesion is mild. With more severe insufficiency, the *electrocardiogram* shows prominent bifid P waves, signs of left ventricular hypertrophy, and associated right ventricular hypertrophy if pulmonary hypertension is present. *Roentgenographically*, prominence of the left atrium and ventricle can be seen. Congestion of perihilar vessels, a sign of pulmonary venous hypertension, may also be evident. Calcification of the mitral valve is rare in children. *Echocardiography* shows enlargement of the left atrium and ventricle, and Doppler studies demonstrate the severity of the mitral regurgitation. *Heart catheterization* and left ventriculography are considered only if diagnostic questions are not totally resolved by noninvasive assessment. The degree of opacification of the left atrium during left ventriculography is used as a qualitative assessment of the severity of mitral insufficiency.

Complications.

Severe mitral insufficiency may result in cardiac failure that may be precipitated by progression of the rheumatic process, the onset of atrial fibrillation, or infective endocarditis. The effects of chronic mitral insufficiency may become manifested after many years and include right ventricular failure and atrial and ventricular arrhythmias.

Treatment.

In patients with mild mitral insufficiency, prophylaxis against recurrences of rheumatic fever is all that is required. Treatment of complicating heart failure (see Chapter 434), arrhythmias (see Chapter 428), and infective endocarditis (see Chapter 429) is described elsewhere. Afterload-reducing agents (captopril, hydralazine) may reduce the regurgitant volume and preserve left ventricular function. Surgical treatment is indicated for patients who despite adequate medical therapy have recurrent episodes of heart failure, dyspnea with moderate activity, and progressive cardiomegaly, often with pulmonary hypertension. Although annuloplasty provides good results in some children and adolescents, valve replacement may be required. Prophylaxis against bacterial endocarditis is warranted in these patients for dental or other surgical procedures. The routine antibiotics taken by these patients for rheumatic fever prophylaxis are insufficient to prevent endocarditis.

Mitral Stenosis

Pathophysiology.

Mitral stenosis of rheumatic origin results from fibrosis of the mitral ring, commissural adhesions, and contracture of the valve leaflets, chordae, and papillary muscles over

time. It takes 10 yr or more for the lesion to become fully established, although the process may occasionally be accelerated. Rheumatic mitral stenosis is seldom encountered before adolescence and is not usually recognized until adult life. Significant mitral stenosis results in increased pressure and enlargement and hypertrophy of the left atrium, pulmonary venous hypertension, increased pulmonary vascular resistance, and pulmonary hypertension. Right ventricular and atrial dilatation and hypertrophy ensue and are followed by right-sided heart failure.

Clinical Manifestations.

Generally, the correlation between symptoms and the severity of obstruction is good. Patients with mild lesions are asymptomatic. More severe degrees of obstruction are associated with exercise intolerance and dyspnea. Critical lesions can result in orthopnea, paroxysmal nocturnal dyspnea, and overt pulmonary edema, as well as atrial arrhythmias. When pulmonary hypertension has developed, right ventricular dilatation may result in functional tricuspid insufficiency, hepatomegaly, ascites, and edema. Hemoptysis caused by rupture of bronchial or pleurohilar veins and, occasionally, by pulmonary infarction may occur.

Jugular venous pressure is increased in severe disease with heart failure, tricuspid valve disease, or severe pulmonary hypertension. In mild disease, heart size is normal; however, moderate cardiomegaly is usual with severe mitral stenosis. Cardiac enlargement can be massive when atrial fibrillation and heart failure supervene. A parasternal right ventricular lift is palpable when pulmonary pressure is high. The principal auscultatory findings are a loud 1st heart sound, an opening snap of the mitral valve, and a long, low-pitched, rumbling mitral diastolic murmur with presystolic accentuation at the apex. The mitral diastolic murmur may be virtually absent in patients who are in heart failure. A holosystolic murmur secondary to tricuspid insufficiency may be audible. In the presence of pulmonary hypertension, the pulmonic component of the 2nd heart sound

is accentuated. An early diastolic murmur may be caused by associated aortic insufficiency or secondary pulmonary valvular insufficiency.

Electrocardiograms and *roentgenograms* are normal if the lesion is mild; as the severity increases, prominent and notched P waves and varying degrees of right ventricular hypertrophy become evident. Atrial fibrillation is a common late manifestation. Moderate or severe lesions are associated with roentgenographic signs of left atrial enlargement and prominence of the pulmonary artery and right-sided heart chambers; calcifications may be noted in the region of the mitral valve. Severe obstruction is associated with a redistribution of pulmonary blood flow so that the apices of the lung have greater perfusion (the reverse of normal). *Echocardiography* shows distinct narrowing of the mitral orifice during diastole and left atrial enlargement, and Doppler can estimate the transmitral pressure gradient. *Cardiac catheterization* quantitates the diastolic gradient across the mitral valve and the degree of elevation of pulmonary arterial pressure.

Treatment.

Intervention is indicated in patients with clinical signs and hemodynamic evidence of severe obstruction but before the severe manifestations outlined earlier. Surgical valvotomy or balloon catheter mitral valvuloplasty generally yields good results; valve replacement is avoided unless absolutely necessary. Balloon valvuloplasty is indicated for symptomatic, stenotic, pliable, noncalcified valves of patients without atrial arrhythmias or thrombi.

Aortic Insufficiency

In chronic rheumatic aortic insufficiency, sclerosis of the aortic valve results in distortion and retraction of the cusps. Regurgitation of blood leads to volume overload with dilatation and hypertrophy of the left ventricle. Combined mitral and aortic insufficiency is more common than aortic involvement alone.

Clinical Manifestations.

Symptoms are unusual except in severe aortic insufficiency. The large stroke volume and forceful left ventricular contractions may result in palpitations. Excessive sweating and heat intolerance are related to vasodilation. Dyspnea on exertion can progress to orthopnea and pulmonary edema; angina may be precipitated by heavy exercise. Nocturnal attacks with sweating, tachycardia, chest pain, and hypertension may occur.

The pulse pressure is wide with bounding peripheral pulses. Systolic blood pressure is elevated, and diastolic pressure is lowered. In severe aortic insufficiency, the heart is enlarged, with a left ventricular apical heave. A diastolic thrill may be present. The typical murmur begins immediately with the 2nd heart sound and continues until late in diastole. The murmur is heard over the upper and midleft sternal border with radiation to the apex and the aortic area. Characteristically, it has a high-pitched blowing quality and is easily audible in full expiration with the diaphragm of the stethoscope placed firmly on the chest and the patient leaning forward. A systolic ejection murmur is frequent because of the increased stroke volume. An apical presystolic murmur (Austin Flint murmur) resembling that of mitral stenosis is sometimes heard and is a result of the large regurgitant aortic flow in diastole that prevents the mitral valve from opening fully.

Roentgenograms show enlargement of the left ventricle and aorta. The *electrocardiogram* may be normal, but in advanced cases it reveals signs of left ventricular hypertrophy and strain with prominent P waves. The *echocardiogram* shows a large left ventricle and diastolic mitral valve flutter or oscillation caused by regurgitant flow hitting the valve leaflets. Doppler studies demonstrate the degree of aortic runoff into the left ventricle. *Cardiac catheterization* is necessary only when the echocardiographic data are equivocal.

Prognosis and Treatment.

Mild and moderate lesions are well tolerated. Many adolescents with severe

regurgitation are symptom free and tolerate advanced lesions into the 3rd–4th decades. Unlike mitral insufficiency, aortic insufficiency does not regress. Patients with combined lesions during the episode of acute rheumatic fever may have only aortic involvement 1–2 yr later. Treatment consists of afterload reducers (e.g., captopril, hydralazine) and prophylaxis against recurrence of acute rheumatic fever and the development of infective endocarditis. Surgical intervention (valve replacement) should be carried out well in advance of the onset of heart failure, pulmonary edema, or angina, when signs of decreasing myocardial performance become evident as manifested by increasing left ventricular dimensions on the echocardiogram. Surgery is considered when early symptoms are present, ST-T wave changes are seen on the electrocardiogram, or evidence of decreasing left ventricular ejection fraction is noted.

Tricuspid Valve Disease

Primary tricuspid involvement is rare after rheumatic fever. *Tricuspid insufficiency* is more common secondary to right ventricular dilatation resulting from unrepaired left-sided lesions. The signs produced by tricuspid insufficiency include prominent pulsations of the jugular veins, systolic pulsations of the liver, and a blowing holosystolic murmur at the lower left sternal border that increases in intensity during inspiration. Concomitant signs of mitral or aortic valve disease, with or without atrial fibrillation, are frequent. Signs of tricuspid insufficiency decrease or disappear when heart failure produced by the left-sided lesions is successfully treated. Tricuspid valvuloplasty may be required in rare cases.

Pulmonary Valve Disease

Pulmonary insufficiency usually occurs on a functional basis secondary to pulmonary hypertension and is a late finding with severe mitral stenosis. The murmur (Graham Steell murmur) is similar to that of aortic insufficiency, but peripheral arterial signs (bounding pulses) are absent. The correct diagnosis is confirmed by two-dimensional echocardiography and Doppler studies.

Section 6 - *Diseases of the Myocardium and Pericardium*

Daniel Bernstein

Chapter 431 - Diseases of the Myocardium

In children, myocardial function is relatively unimpaired early in the course of the majority of congenital heart lesions. In some congenital lesions (left-to-right shunts), the myocardium may even be functioning at a supranormal level (high-output state). Children with unoperated congenital heart disease, long-standing volume, pressure overload, or chronic hypoxia may eventually experience myocardial dysfunction. In most children with diseases of the myocardium, causes other than congenital heart disease are predominant (Table 431–1).

Cardiomyopathies were divided into primary or idiopathic (those with unknown cause) and secondary (those resulting from infections, endocrine disorders, metabolic and nutritional diseases, neuromuscular diseases, blood diseases, and tumors). Molecular biology has identified specific causes in many patients who were classified as "idiopathic." In some, specific gene defects have been identified; in others, polymerase chain reaction (PCR) has detected evidence of a viral genome, thus suggesting previous or chronic viral myocarditis. A useful scheme for classifying cardiomyopathies is based on the predominant structural and functional abnormalities: *dilated cardiomyopathy, hypertrophic cardiomyopathy,* and *restrictive cardiomyopathy* (Table 431–2). The prevalence of cardiomyopathy in the newborn period is 10/100,000 live births, whereas for all children the prevalence is 36/100,000 for dilated cardiomyopathy and 2/100,000 for hypertrophic and restrictive cardiomyopathy.

431.1 Dilated Cardiomyopathy

Pathophysiology.

Dilated cardiomyopathy is characterized by cardiomegaly secondary to extensive dilatation of the ventricles, most prominently the left. Varying degrees of ventricular hypertrophy are also present. The cause in the vast majority of pediatric cases is still unknown *(idiopathic dilated cardiomyopathy)* but may have a genetic basis; a remote history of viral illness in many patients suggests that the disease may be a sequela of a previous myocarditis. Active myocarditis is identified in 2–15% of patients. In as many as 20% of cases, the disease is recognized as familial, with autosomal dominant, autosomal recessive, X-linked, and mitochondrial inheritance patterns (see Table 431–2). Potential gene loci for the autosomal dominant form include chromosome 1p1-1q1 and chromosome 3p25. For the X-linked form, the Xp21 region containing the dystrophin gene is implicated. Mitochondrial myopathies may be due to mutations of either nuclear DNA (in which inheritance will follow mendelian genetic patterns) or mitochondrial DNA (which is inherited solely from the mother). Mitochondrial abnormalities leading to dilated cardiomyopathy involve enzymes of the electron transport chain (nuclear DNA) or enzymes of fatty acid oxidation (mitochondrial DNA). Patients with dilated cardiomyopathy may have infectious causes other than viral infection, including endocrine disorders such as hypothyroidism, metabolic disorders such as storage disease, nutritional deficiency, exposure to cardiotoxic agents such as doxorubicin, systemic disorders such as connective tissue disease, and familial muscular or neuromuscular disorders such as the muscular dystrophies. Specific cardiac causes include congenital and acquired abnormalities of the coronary arteries, tachyarrhythmias, and familial hypercholesterolemia.

Myocardial biopsy early in the disease process may be useful; a specific cause is rarely found when biopsy samples are obtained after long-standing disease, in which case the histologic findings consist mainly of areas of fibrosis and compensatory hypertrophy. A viral origin of many of these "idiopathic" cases may be detected with PCR. A complete family history is important, and unless a viral diagnosis is confirmed, first-degree family members should be screened for subclinical cardiomyopathy by echocardiography. DNA studies on both affected and nonaffected family members may help determine the specific gene defect. In several states, neonatal screening is becoming available for some of the mitochondrial disorders of fatty acid oxidation.

Clinical Manifestations.

All age groups may be affected. Usually, the onset is insidious, but sometimes symptoms of heart failure occur suddenly. Irritability, anorexia, abdominal pain, cough from pulmonary congestion, and dyspnea with exertion are common. Infants and younger children tend to have respiratory symptoms and failure to thrive, whereas older children and adolescents often initially have primarily abdominal complaints such as nausea and anorexia. Although the typical sign of pulmonary edema is the presence of rales, younger infants can exhibit wheezing. When the disease is fully established, the skin is cool and pale, the arterial pulse is decreased, pulse pressure is narrow, and tachycardia is present. Jugular venous pressure is increased, and hepatomegaly and edema are common. The heart is enlarged, and holosystolic murmurs of mitral and tricuspid insufficiency may be present. A summation gallop rhythm is usually audible.

Diagnosis.

The *electrocardiogram* shows a combination of atrial enlargement, varying degrees

of left or right ventricular hypertrophy, and nonspecific T-wave abnormalities. The *roentgenogram* confirms the cardiomegaly. Pulmonary congestion and pleural effusions may also be present. Often, the initial diagnosis of dilated cardiomyopathy is suspected when a chest roentgenogram is performed to evaluate a suspected pneumonia. The *echocardiogram* shows dilatation of the left atrium and ventricle and poor contractility. The right ventricle may also be affected. Doppler studies show decreased flow velocity through the aortic valve and mitral regurgitation. In long-standing cases, evidence of pulmonary hypertension may exist.

Prognosis and Management.

The course of the disease is usually progressively downhill, although some patients may remain stable for years. Vigorous treatment of heart failure (see Chapter 434) may result in temporary remission, but relapses are common, and in time patients tend to become resistant to therapy. Once this point is reached, the prognosis for survival beyond a year is poor. Serious complications include ventricular arrhythmias leading to syncope and sudden death, as well as pulmonary or systemic emboli from intracardiac thrombi. Patients with severely depressed myocardial function should be monitored closely for arrhythmias and, if present, treated aggressively with

antiarrhythmic agents or an implantable cardioverter-defibrillator (ICD). They should also receive systemic anticoagulation with warfarin. The use of ß-adrenergic blocking agents such as metoprolol and carvedilol in adults with cardiomyopathy has resulted in improvement in exercise capacity and a reduction in hospitalization and mortality. The initial experience with these drugs in children is encouraging. A trial of oral carnitine is worthwhile. When medical therapy fails, heart transplantation has been effective in infants and children with dilated cardiomyopathy (see Chapter 435). Because of the scarcity of pediatric donor organs, patients with cardiomyopathy should be referred to a pediatric heart transplant center for an initial evaluation early in the course of their disease.

Neuromuscular Diseases.

Heart disease is common in patients with *Friedreich ataxia* (see Chapter 590.1), which chiefly affects the left ventricle and results in a dilated or restrictive cardiomyopathy. In some patients, exercise intolerance, chest pain, and heart failure have been the initial symptoms. Arrhythmias may also occur and consist of atrial tachycardia, fibrillation, or extrasystoles. In *Duchenne muscular dystrophy* (see Chapter 600.1), 50% of children have postmortem evidence of myocardial involvement similar to that of the striated muscle. Most often the cardiac symptoms are overshadowed by peripheral muscular and pulmonary complications, although separating disability caused by cardiac failure from that caused by peripheral muscle or pulmonary complications can be difficult. The electrocardiogram may reveal tachycardia, abnormalities in P waves, a short P-R interval, and abnormal Q and T waves. Minimal evidence of right or left ventricular hypertrophy may also be noted. In the less severe forms of muscular dystrophy, for example, *Becker dystrophy,* cardiac involvement may be more prominent and the primary cause of exercise intolerance and respiratory symptoms. Other X chromosome–linked dilated cardiomyopathies have been described without associated skeletal muscle involvement. Some limited experience with heart transplantation exists in patients with the milder Becker dystrophy.

Kawasaki Disease

(see Chapter 156). The arteritis associated with Kawasaki disease initially involves small arterioles, but in the 2nd and 3rd wk of illness, medium-sized arteries become inflamed and aneurysmal dilatation of the coronary arteries may occur. During the healing phase, areas of both coronary dilatation and stenosis may result and can lead to myocardial infarction and death. Myocarditis is a less common sequela of Kawasaki disease but, when present, is manifested as heart failure early in the course.

Autoimmune Diseases.

Rheumatic carditis is described in Chapter 147 and Chapter 430 . The cardiovascular manifestations of juvenile rheumatoid arthritis, systemic lupus erythematosus, periarteritis nodosa, dermatomyositis, and scleroderma are described in Part 15 .

TABLE 431.1-2 -- Cardiomyopathies

	Dilated	Hypertrophic	Arrhythmogenic Right Ventricular	Restrictive

AD = autosomal dominant inheritance; AR = autosomal recessive inheritance; X-L = X-linked inheritance; Mt = mitochondrial inheritance; ACE = angiotensinconverting enzyme; ICD = implantable cardiac defibrillator.

Endocrine Disorders.

Hyperthyroidism (see Chapter 562) produces tachycardia, vasodilation, a wide pulse pressure, cardiac enlargement, and occasionally, atrial fibrillation. Hypothyroidism can produce cardiac dysfunction in adults but seldom produces gross cardiac involvement in children. The electrocardiogram is characterized by bradycardia, low voltage of all complexes (especially the P and T waves), left axis deviation, and prolonged electrical systole. These signs usually disappear within 1 mo after initiation of adequate thyroid therapy. Diabetic cardiomyopathy is rare in children; however, infants of diabetic mothers can experience cardiac hypertrophy and dilatation. Cardiomyopathy may be caused by chronic exposure to elevated catecholamines in patients with pheochromocytoma.

Metabolic and Nutritional Diseases.

Among the vitamin deficiency diseases, *beriberi* (see Chapter 44.2) causes the most conspicuous cardiac damage. In patients with malnutrition such as kwashiorkor, the deficiencies are often multiple, and it may be difficult to separate the cardiac lesion of one nutritional disease from that of another (see Chapter 42.1 and Chapter 42.2). Other nutritional and metabolic causes of cardiac dysfunction include selenium (see Chapter 41.6) and taurine deficiency and carnitine deficiency (Chapter 75.1). In children suffering from malabsorption because of their primary illness, for example, epidermolysis bullosa, nutritional cardiomyopathies may develop as well.

Hematologic Diseases.

In infants and children, severe anemia may be associated with cardiac involvement. Although cardiac output increases when the hemoglobin content is less than about 7?g/dL, significant cardiac enlargement occurs with an extreme reduction in hemoglobin (3–4?g or less). The heart rate is rapid, pulse pressure is widened, and venous pressure is increased. A systolic flow murmur at the apex or along the left sternal border is usual; diastolic murmurs may occur in the same areas, and a gallop rhythm is also common. Electrocardiographic changes include depressed ST segments and flat T waves. In patients with congenital heart lesions, anemia can place extra stress on the heart's ability to maintain adequate oxygen delivery and can result in considerable worsening of heart failure symptoms. *Treatment* is directed toward the cause of the anemia. If blood transfusions are indicated in the presence of cardiomegaly or heart failure, only small volumes (5?mL/kg) of packed red blood cells should be administered at any one time and followed by a dose of diuretic (see Chapter 462). Sometimes, exchange transfusion may be prudent to avoid an acute increase in blood volume.

Disorders of the Coronary Arteries.

Anomalous origin of the left coronary artery from the pulmonary artery is one of the major causes of myocardial ischemia in infants (see Chapter 425.2). Anomalous origin of one of the coronaries from the aorta may result in its course running between the aorta and pulmonary artery (“suicide coronary”) and lead to myocardial ischemia and infarction with exercise. Coronary calcinosis is a rare disorder in infants and children in which the coronary arteries are tortuous and calcareous. Other blood vessels may be similarly involved. The onset of cardiac failure is sudden; death usually occurs in infancy. Rare coronary artery malformations include coronary ostial stenosis and coronary artery stenosis in the setting of supravalvular aortic stenosis (see Chapter 420.5). Patients with homozygous familial hypercholesterolemia may have a propensity for coronary atherosclerosis at an early age. Patients who have undergone heart transplantation are at risk for the development of graft coronary artery disease (see Chapter 435).

Doxorubicin (Adriamycin) Cardiotoxicity.

This chemotherapeutic agent can cause acute myocarditis but more often results in chronic dilated cardiomyopathy. The most common manifestation is a severe, chronic, dose-dependent cardiomyopathy, which occurs in about 30% of patients when the total cumulative dose exceeds 550?mg/m^2 but may be seen occasionally in patients after doses as low as 200?mg/m^2 . One study has shown abnormalities in the echocardiographic indices of left ventricular

---

function (wall stress) in as many as 65% of children receiving doses larger than 220?mg/m^2 . When radiation therapy is combined with doxorubicin, the risk of cardiac damage is even greater.

Cardiomyopathy may become manifested months or even years after doxorubicin treatment. Cardiomegaly is principally due to left ventricular and left atrial enlargement. T-wave flattening or inversion is nonspecific evidence of cardiac involvement. Acute electrocardiographic changes, including a long Q-T interval, may be present in 40% of patients immediately after a single dose. Early changes in cardiac function, even in the absence of symptoms, may be detected by serial echocardiograms or radionuclide (MUGA [multigated acquisition]) scans, but no method is totally able to predict which patients are at risk. The child's condition may remain clinically stable for many years, even with decreased fractional shortening. Once symptoms of heart failure develop, the case fatality rate is as high as 30–50%. Cardiac transplantation has been used with success in these patients (see Chapter 435).

Acute myocarditis is less common and typically occurs during the course of administration of the drug. It is frequently reversible, and the long-term prognosis may be somewhat better. Supportive treatment consists of anticongestive medications such as digoxin, diuretics, and afterload-reducing agents.

Ipecac Cardiac Toxicity.

Cardiac toxicity can occur with chronic intentional ipecac abuse secondary to anorexia nervosa or bulimia nervosa. Manifestations include chest pain, tachycardia, dyspnea, hypotension, arrhythmias, flattening and inversion of T waves, ST segment abnormalities, prolongation of the Q-T and P-R intervals, cardiac failure, and potentially death. Differentiating the cardiac abnormalities caused by ipecac from those of chronic starvation, abnormal diets, and electrolyte abnormalities may be difficult.

431.2 Hypertrophic Cardiomyopathy

Pathophysiology.

Hypertrophic cardiomyopathies in children may be secondary to obstructive congenital heart disease (critical aortic stenosis, coarctation of the aorta) or to an inborn error of metabolism (glycogen storage disease or mucopolysaccharidosis), or it may be idiopathic. This latter condition is known variably as *hypertrophic cardiomyopathy, hypertrophic obstructive cardiomyopathy, idiopathic hypertrophic subaortic stenosis,* or *asymmetric septal hypertrophy,* although subaortic obstruction is present in only about 25% of cases. Massive ventricular hypertrophy with principal involvement of the ventricular septum characterizes the disease, but all portions of the left ventricle and sometimes the right ventricle can be affected. Varying degrees of myocardial fibrosis are also present. The mitral valve is displaced anteriorly by hypertrophy of the papillary muscles, and the left ventricular cavity is distorted by the massive generalized hypertrophy. Microscopically, patchy areas of abnormally thick and short muscle fibers are arranged in circular collections and interspersed among normal as well as hypertrophied muscle fibers. Electron microscopy shows a disarray of myofibrils and myofilaments.

The hypertrophic and fibrosed muscle has decreased distensibility (compliance), so resistance to left ventricular filling occurs; systolic pumping function remains intact (or may even be hyperdynamic) until late in the course of the disease. Obstruction to left ventricular outflow develops in 25% of patients because of apposition of the abnormally placed anterior mitral leaflet against the hypertrophied septum. Varying degrees of mitral valve insufficiency are also common.

Epidemiology.

Hypertrophic cardiomyopathy is most often inherited in an autosomal dominant pattern with wide variability in penetrance. Manifestations can begin at any age. Siblings of the proband may not be affected as children but may show evidence of the disease as they reach adolescence and adulthood. Mutations of the cardiac ß-myosin heavy-chain gene on chromosome 14 are responsible for 30–40% of cases of familial hypertrophic cardiomyopathy (see Table 431–2). Other mutations include the cardiac troponin T gene on chromosome 1q3, a-tropomyosin on chromosome 15q2, and cardiac myosin-binding protein C on chromosome 11q11. Genetic testing may eventually make it possible to predict which patients are more likely to suffer from arrhythmias and sudden death. Other gene alterations associated with hypertrophic cardiomyopathy include those of the mitochondrial respiratory chain enzymes, which give rise to a maternal pattern of inheritance.

In childhood, hypertrophic cardiomyopathy may be somewhat different from the disease in adults in that children have a greater tendency for the development of left and right ventricular outflow obstruction. The left ventricular wall may be diffusely thickened, as opposed to only the septal portion being thickened.

Clinical Manifestations.

Many children are asymptomatic, and about 50% of cases are first evaluated because of a heart murmur or because another family member has come to medical attention. In others, the clinical pattern is dominated by weakness, fatigue, dyspnea on effort, palpitations, angina pectoris, dizziness, and syncope. Even asymptomatic children have a risk of sudden death. The pulse can be brisk because of the early

systolic ejection of blood from the ventricle. A prominent left ventricular lift and double apical impulse may be noted. The 1st and 2nd heart sounds are usually normal. The rarity of systolic ejection clicks helps differentiate hypertrophic obstructive cardiomyopathy from valvular aortic stenosis. The systolic murmur is ejection in type and of medium intensity; it is heard maximally at the left sternal edge and apex. The murmur may increase shortly after exercise is discontinued, during the Valsalva maneuver, or on assumption of the erect position.

Diagnosis.

The *electrocardiogram* shows left ventricular hypertrophy with or without ST segment depression and T-wave inversion. Signs of the Wolff-Parkinson-White syndrome and other intraventricular conduction defects may be present. *Roentgenograms* demonstrate mild cardiomegaly with prominence of the left ventricle. The *echocardiogram* shows left ventricular hypertrophy predominantly affecting the interventricular septum, although concentric hypertrophy, systolic anterior motion of the anterior leaflet of the mitral valve, and premature closure of the aortic valve are also seen. Doppler studies demonstrate the presence of a left ventricular outflow tract gradient, which usually occurs in mid to late systole, when the muscular obstruction to outflow is maximal.

Echocardiography has largely replaced *cardiac catheterization* for initial diagnosis, although catheterization is useful in assessing a patient's candidacy for surgery. Many patients who do not have a left ventricular outflow tract gradient at rest may acquire a significant gradient after the administration of isoproterenol, amyl nitrite, or nitroglycerin. Left ventriculography shows encroachment on the left ventricular cavity by the hypertrophied muscle, especially by the interventricular septum. Midsystolic cavity obliteration occurs in more severe cases. Mitral insufficiency is common. A discrete subaortic obstruction with secondary muscular hypertrophy should be ruled out because surgical management of discrete subaortic stenosis is much more effective (see Chapter 420.5). The *prognosis* of hypertrophic cardiomyopathy in an individual patient is unpredictable. Asymptomatic patients may remain stable for years. Some patients progress to chronic heart failure, whereas others are at risk for sudden death from arrhythmia. The clinical course of other affected family members may be of some use in stratifying risk in an affected child.

Treatment.

No standardized therapy has been established. Competitive sports and strenuous physical activity should be prohibited because most sudden deaths occur during or immediately after vigorous physical exertion. Digitalis or aggressive diuresis is contraindicated in most patients. Infusion of isoproterenol or other inotropic agents should also be avoided other than for diagnostic purposes in the controlled environment of the catheterization laboratory. ß-Adrenergic blocking agents (propranolol) and calcium channel blocking agents (verapamil, nifedipine) have been used with some success in decreasing the degree of outflow obstruction and slowing the development of hypertrophy; these drugs do not necessarily affect the long-term prognosis and do not reduce the incidence of sudden death. Calcium channel blockers should not be used during infancy because of the increased risk of cardiovascular collapse. Patients with arrhythmias should be treated aggressively with either pharmacologic agents or an ICD. A pacemaker has been used to alter septal depolarization in some patients, although this modality is less effective in reducing the gradient and may be reserved for patients who are high surgical risks. Surgery involving ventricular septal myotomy has been successfully accomplished in some patients, especially in those with disabling angina or syncope associated with left ventricular outflow tract obstruction (resting or provoked gradient of =50?mm Hg). Although surgical reduction of the outflow tract gradient may improve symptoms, it does not reduce the risk of sudden death. Mitral valve replacement may be needed if the obstruction cannot be alleviated.

Hypertrophic Cardiomyopathy in Infants of Diabetic Mothers.

In *infants of diabetic mothers,* a transient form of hypertrophic cardiomyopathy may be encountered with or without left ventricular outflow tract obstruction. The increased left ventricular mass usually regresses within several months (Chapter 96.1).

Corticosteroids in Premature Infants.

Premature infants who are receiving *corticosteroids* for chronic lung disease may also experience transient hypertrophic cardiomyopathy, which usually resolves rapidly with cessation of steroid therapy.

Glycogen Storage Disease.

Cardiac as well as skeletal muscles are affected in the generalized form of glycogen storage disease known as type II or *Pompe disease* (see Chapter 76.1). The cardiomegaly is massive, but murmurs are insignificant. Pulmonary atelectasis with secondary infection is common and related to compression by the enlarged heart. The *electrocardiogram* is characteristic and shows prominent P waves, a short P-R interval, massive QRS voltage, signs of isolated left or biventricular hypertrophy, and intraventricular conduction delays. *Roentgenograms* confirm the striking cardiomegaly with prominence of the left ventricle. The echocardiogram shows severe ventricular hypertrophy. The prognosis is poor. Recombinant enzyme therapy holds some promise to improve the outcome.

431.1 Restrictive Cardiomyopathy

Poor ventricular compliance is the major abnormality in restrictive cardiomyopathies, and inadequate filling of the ventricular cavities occurs during diastole and results in *clinical manifestations* that closely simulate those of constrictive pericarditis (see Chapter 432.1). In its full-blown form, restrictive cardiomyopathy results in dyspnea, edema, ascites, hepatomegaly, increased venous pressure, and pulmonary congestion. The heart is mildly or moderately enlarged, and murmurs are nonspecific. The electrocardiogram shows very prominent P waves, often normal QRS voltage, ST segment depression, and T-wave inversion. Roentgenographic examination shows mild to moderate cardiomegaly. The echocardiogram shows markedly enlarged atria and small to normal-sized ventricles with often preserved systolic function but highly abnormal filling characteristics by Doppler

echocardiography. *Differential diagnosis* from constrictive pericarditis is critical, though difficult, because the latter can be treated surgically. Restrictive cardiomyopathy may be idiopathic, or it may be associated with a systemic disease such as scleroderma, amyloidosis, or sarcoidosis; an inborn error of metabolism (mucopolysaccharidosis); hypereosinophilic syndrome; malignancies; or radiation therapy. It may also result from a congenital abnormality such as isolated noncompaction of the left ventricular myocardium. The *prognosis* for restrictive cardiomyopathy is generally poor, and clinical deterioration can be rapid. Treatment is directed toward relief of heart failure, although these patients may show a poor response to standard heart failure management (see Chapter 434); calcium channel blocking agents have been used by some in an effort to increase diastolic compliance. Antiarrhythmic agents are used as required, and anticoagulation with warfarin is indicated for lesions with an increased risk of mural thrombosis and stroke. Cardiac transplantation has been used effectively in some of these patients as long as multiple organ involvement from systemic disease is not present. Referral to a transplant center should be considered as soon as a diagnosis of restrictive cardiomyopathy is made.

Löffler Hypereosinophilic Syndrome.

This disorder produces severe multisystem dysfunction (skin, lungs, nervous system, liver), and the predominant cause of death is restrictive cardiomyopathy with endocardial fibrosis of the mitral and tricuspid valves and the right and left ventricles. The subsequent formation of endocardial thrombi results in embolization. Löffler syndrome should be distinguished from nonrestrictive, nonfibrotic acute *eosinophilic necrotizing myocarditis,* an acute rapidly fatal illness, and from *hypersensitivity myocarditis* (characterized by fever, rash, tachycardia, eosinophilia, drug allergy, and arrhythmias). Steroids and cytotoxic agents may be beneficial in the hypereosinophilic syndromes. Anticoagulant therapy may reduce the incidence of thromboembolism.

Mucopolysaccharidosis.

In this disorder, most commonly *Hurler syndrome,* mucopolysaccharides accumulate in many organs, including the heart and great vessels (see Chapter 77). The most pronounced lesions are found in the valves and coronary arteries, but abnormalities in the pericardium and aorta are not uncommon. The heart may be moderately enlarged, with electrocardiographic signs of left ventricular hypertrophy. Cardiac murmurs may result from insufficiency and stenosis of the mitral and aortic valves. Sometimes the pulmonary and tricuspid valves are also involved. Coronary arterial disease may result in angina, which perhaps explains the frequent occurrence of sudden death. The prognosis is poor.

Isolated Noncompaction of the Left Ventricle.

This cardiomyopathy of unknown cause results in elements of both left ventricular restriction and dilatation. The condition may be diagnosed at any age, from infancy to young adulthood, and the severity of congestive heart failure varies. The echocardiogram is diagnostic and shows a specific pattern of left ventricular hypertrophy with deep muscular crypts. Patients may be at risk for ventricular arrhythmias and sudden death, as well as mural thromboses and stroke. Although some patients may remain stable for years, others may deteriorate rapidly. Cardiac transplantation has been used successfully in this group of patients.

431.3 Myocarditis

Myocarditis refers to inflammation, necrosis, or myocytolysis and may be caused by many infectious, connective tissue, granulomatous, toxic, or idiopathic processes affecting the myocardium with or without associated systemic manifestations of the disease process or involvement of the endocardium or pericardium (see Table 431–1). Coronary pathology is

uniformly absent. The most common manifestation is heart failure, although arrhythmias and sudden death may be the 1st detectable signs. Viral infections are the most common cause.

Etiology and Epidemiology.

The true incidence of viral myocarditis in children is unknown because many mild cases go undetected. Viral myocarditis is typically a sporadic, but occasionally an epidemic illness. Its manifestations are to some degree age dependent: in early infancy, viral myocarditis often occurs as an acute, fulminant disease; in toddlers and young children, it occurs as an acute, but less fulminant myopericarditis; and in older children and adolescents, it is often asymptomatic and comes to clinical attention primarily as a precursor to idiopathic dilated cardiomyopathy. The most common causative agents are coxsackievirus B and adenovirus, although many known viral agents have been implicated.

Pathophysiology.

Acute viral myocarditis may produce a fulminant inflammatory process characterized by cellular infiltrates, cell degeneration and necrosis, and subsequent fibrosis. Viral myocarditis may also become a chronic process with persistence of viral RNA or DNA (but not infectious virus particles) in the myocardium. Chronic inflammation is then perpetuated by the host immune response, which includes T lymphocytes activated against viral-host antigenic alterations. Such cytotoxic lymphocytes and natural killer cells, together with persistent and possibly defective viral replication, may impair myocyte function without obvious cytolysis. Alternatively, the persistent viral infection may alter the expression of major histocompatibility complex antigens, with resultant exposure of neoantigens to the immune system. In addition, some viral proteins may share antigenic epitopes with host cells, which results in autoimmune damage to the antigenically related myocyte. Cytokines such as tumor necrosis factor-a and interleukin 1 may be released and participate in initiation of the altered immune response. The net final result of chronic viral-associated inflammation is often dilated cardiomyopathy.

Clinical Manifestations.

Signs and symptoms depend on the patient's age and the acute or chronic nature of the infection. A *neonate* may initially have fever, severe heart failure, respiratory distress, cyanosis, distant heart sounds, weak pulses, tachycardia out of proportion to the fever, mitral insufficiency caused by dilatation of the valve annulus, a gallop rhythm, acidosis, and shock. Evidence of viral hepatitis, aseptic meningitis, and an associated rash may be present. In the most fulminant form, death may occur within 1–7 days of the onset of symptoms. The chest roentgenogram demonstrates an enormously enlarged heart and pulmonary edema; the electrocardiogram reveals sinus tachycardia, reduced QRS complex voltage, and ST segment and T-wave abnormalities. Arrhythmias may be the first clinical manifestation and, in the presence of fever and a large heart, strongly suggest acute myocarditis.

An *older patient* with acute myocarditis may also initially be seen with acute congestive heart failure; however, more commonly, patients have a gradual onset of congestive heart failure or a sudden onset of ventricular arrhythmias. In these patients, the acute infectious phase has usually passed and an idiopathic dilated cardiomyopathy is present (see Chapter 431.1).

Diagnosis.

The sedimentation rate and heart enzymes (creatine phosphokinase, lactate dehydrogenase) may be elevated in acute or chronic myocarditis. If positive, serum viral titers are helpful; negative titers do not eliminate the diagnosis. Paired studies involving PCR of ventricular biopsy and serum samples have shown viral genome routinely present in cardiac samples yet absent in peripheral blood. *Echocardiography* demonstrates poor ventricular function and often a pericardial effusion, mitral valve regurgitation, and the absence of coronary artery or other congenital heart lesions. Myocarditis can be confirmed by endomyocardial biopsy. Biopsy is performed during cardiac catheterization and can also be used to detect other causes of cardiomyopathy (storage disease, mitochondrial defects). PCR can identify specific viral RNA or DNA.

Differential Diagnosis.

The predominant diseases mimicking acute myocarditis include carnitine deficiency, hereditary mitochondrial defects, idiopathic dilated cardiomyopathy, pericarditis, fibroelastosis of the endocardium, and anomalous origin of the left coronary artery (see Table 431–1).

Treatment.

The approach to treating acute myocarditis involves supportive measures for severe congestive heart failure (see Chapter 434). Dopamine or epinephrine may be helpful in those with poor cardiac output and systemic hypotension. However, all inotropic agents, including digoxin, should be used with caution because patients with myocarditis may be more susceptible to the arrhythmogenic properties of these agents. Digoxin is often started at half the normal dosage. Pericardiocentesis should be performed in patients with evidence of cardiac tamponade, and culture of pericardial fluid may yield the offending viral agent. Arrhythmias should be treated aggressively and may require the use of intravenous amiodarone to achieve adequate control. For infants and children in cardiogenic shock, extracorporeal membrane oxygenation may be indicated. In larger children and adolescents, implantation of a left ventricular assist device has been performed, usually as a bridge to heart transplantation, which is the treatment of choice in those with refractory heart failure (see Chapter 435). The role of corticosteroids in the treatment of acute viral myocarditis is controversial. In a small series of pediatric patients, treatment with prednisone (2?mg/kg daily, tapered to 0.3?mg/kg daily over a period of 3 mo) was effective in reducing myocardial inflammation and improving cardiac function. Relapse was noted to occur when immunosuppression was discontinued. Trials in adult patients have shown mixed results. Specific antiviral therapy for enterovirus (pleconaril) or Epstein-Barr virus (acyclovir) may be effective.

Prognosis.

The outcome of symptomatic neonates with acute viral myocarditis has been poor, but pleconaril therapy has been quite effective in those infected with enteroviruses. Patients with lesser symptoms have a better prognosis, and complete resolution has been described. The outcome of older patients with chronic dilated cardiomyopathy associated with previous viral infection is also poor without therapy. These patients continue to have dilatation, fibrosis, and deteriorating cardiac function. Spontaneous resolution has occurred in various adult studies in 10–50% of patients. However, as many as 50% of untreated older patients die within 2 yr of diagnosis and 80% within 8 yr without heart transplantation.

431.4 Nonviral Causes of Myocarditis

Bacterial Infections.

In *diphtheria* (see Chapter 172), the toxin of the bacillus may produce peripheral circulatory failure or toxic myocarditis within the 1st 2 wk of the disease. In addition to therapy for diphtheria, treatment of cardiogenic shock is essential. Diphtheritic toxic myocarditis is characterized by the development of atrioventricular block, bundle branch block, or extrasystoles. Heart failure occurs later and is associated with cardiac enlargement and a gallop rhythm. In addition to the arrhythmia, the electrocardiogram shows ST segment depression and T-wave inversion in most leads. The immediate prognosis is grave (about 50% mortality). Treatment includes strict bed rest until all signs of myocarditis have disappeared, as well as management of arrhythmias, including cardiac pacing. Digitalis is reserved for patients with frank congestive heart failure, but this drug must be used with care because of the possibility of increased myocardial sensitivity.

In many *systemic bacterial infections,* circulatory involvement is manifested as peripheral circulatory collapse or toxic myocarditis. Toxic myocarditis, as evidenced by tachycardia, a gallop

---

rhythm, and cardiac enlargement, may complicate pneumonia, infective endocarditis, and septicemia. A myocardial depressant factor may produce an acute toxic

cardiomyopathy. The prognosis depends on the ability to control the primary infection.

Rickettsial Diseases.

Rocky Mountain spotted fever (see Chapter 210.1) may be complicated by hypotension and peripheral vascular collapse. This complication has been attributed to the general vasculitis characteristic of the disease, but acute myocarditis may be a contributing factor.

Parasitic and Fungal Infections.

Lesions in the myocardium have been described in association with *histoplasmosis, coccidioidomycosis, toxoplasmosis,* and *trichinosis.* In these conditions, the cardiac lesion seldom produces clinical signs of myocarditis. *Actinomycosis* may involve the pericardium and myocardium by direct contiguity to a pulmonary abscess. *Hydatid cysts* of the pericardium may be found on routine roentgenograms of the chest and usually produce symptoms only when they rupture. *Schistosomiasis* may result in pulmonary hypertension and cor pulmonale. *Cruz trypanosomiasis* (Chagas disease) may produce either acute or subacute myocarditis and can lead to sudden death.

431.5 Endocardial Fibroelastosis

Endocardial fibroelastosis (EFE) has been called *fetal endocarditis, endocardial fibrosis, prenatal fibroelastosis, elastic tissue hyperplasia,* and *endocardial sclerosis.* In *primary* EFE, no apparent predisposing valvular lesion or other congenital heart abnormality can be found. In *secondary* EFE, severe congenital heart disease of the left-sided obstructive type (e.g., aortic stenosis or atresia, forms of hypoplastic left heart syndrome, or severe coarctation of the aorta) is present. In *secondary* EFE, the ventricular cavity is often contracted, whereas with primary disease, a dilated left ventricular chamber is seen, usually during infancy. However, in young adults, a contracted form of primary EFE has been observed. No cause for primary EFE has been firmly established, although an association with mumps infection has been implied through analysis of affected myocardial specimens by PCR.

Pathologically, a white, opaque fibroelastic thickening of the endocardium is present, usually in the left ventricle, and it frequently obscures the trabeculation of the inner surfaces of the cardiac chamber. The lesion may spread to involve the valves. Microscopically, the lesion consists of fibroelastic thickening of the endocardium and may result in subendocardial degeneration or necrosis of muscle with vacuolation of muscle fibers. The involved valve leaflets are characterized by myxomatous proliferation with an increase in collagenous elements.

The *clinical manifestations* are variable. Infants, usually those younger than 6 mo who had apparently been in good health, experience severe congestive heart failure, often precipitated by a respiratory infection. Affected infants may manifest dyspnea, cough, anorexia, hepatomegaly, edema, failure to thrive, and recurrent pulmonary infections. Chronic heart failure can be controlled for some time by digitalis and diuretics; however, most patients eventually succumb. Infants in whom valvular lesions or associated congenital cardiovascular defects are predominant usually expire in the 1st mo of life. *Roentgenograms* confirm significant cardiac enlargement (Fig. 431–1). The electrocardiogram is abnormal, with changes indicative of left atrial and left ventricular hypertrophy with strain. The echocardiogram shows a bright-appearing endocardial surface and a dilated, poorly functioning left ventricle.

Treatment is directed toward alleviation of congestive heart failure and prevention of intercurrent infections. End-stage EFE, with signs of heart failure despite maximal medical treatment, is an indication for heart transplantation (see Chapter 435).

Figure 431.5-1 Roentgenogram of a 7-mo-old girl with endocardial fibroelastosis. Note the enlargement of the heart, without a distinctive contour and clear lung fields.

Chapter 432 - Diseases of the Pericardium

Major diseases that involve the pericardium are noted in Box 432–1 . In some diseases, pericardial involvement is one manifestation of a generalized illness; prominence of the pericardial component varies with the disease.

Pathophysiology.

Pericardial inflammation results in an accumulation of fluid in the pericardial space. The fluid varies according to the cause of the pericarditis and may be serous, fibrinous, purulent, or hemorrhagic. **Cardiac tamponade** occurs when the amount of pericardial fluid reaches a level that compromises cardiac function. In a healthy child, 10–15?mL of fluid is normally found in the pericardial space, whereas in an adolescent with pericarditis, fluid in excess of 1,000?mL may accumulate. For every small increment of fluid, pericardial pressure rises slowly; once a critical level is reached, pressure rises rapidly and culminates in severe cardiac compression. Inhibition of ventricular filling during diastole, elevated systemic and pulmonary venous pressure, and if untreated, eventual compromised cardiac output and shock occur.

Clinical Manifestations.

The 1st symptom of pericardial disease is often precordial pain. The major complaint is a sharp, stabbing sensation over the precordium and often the left shoulder and back; the pain may be exaggerated by lying supine and relieved by sitting, especially leaning forward. Because of the absence of sensory innervation of the pericardium, the pain is probably referred pain from diaphragmatic and pleural irritation. Cough, dyspnea, abdominal pain, vomiting, and fever may also occur. The presence of symptoms or signs associated with other organs depends on the cause of the pericarditis.

Many of the findings on physical examination are related to the degree of fluid accumulation in the pericardial sac. The presence of a friction rub is helpful but is a variable sign in acute pericarditis; it usually becomes apparent when the effusion is small. When the effusion is larger, muffled heart sounds may be the only auscultatory finding. Narrow pulses, tachycardia, neck vein distention, and increased **pulsus paradoxus** suggest significant fluid accumulation.

Pulsus paradoxus is caused by the normal slight decrease in systolic arterial pressure during inspiration. With cardiac tamponade, this normal phenomenon is exaggerated, probably because of decreased filling of the left side of the heart with the inspiratory phase of respiration. The degree of pulsus paradoxus is determined with a mercury manometer. The patient is told to breathe normally without exaggeration. By allowing the manometer to fall slowly, the 1st Korotkoff sound will initially be heard intermittently (varying with respirations). This 1st point is noted, and the manometer is then allowed to fall until the 1st Korotkoff sound is heard continuously. The difference between these two systolic pressures is the pulsus paradoxus. A pulsus paradoxus greater than 20?mm Hg in a child with pericarditis is an indicator of the presence of cardiac tamponade; a

- Iatrogenic (catheter related)
- Postpericardiotomy (cardiac surgery)
- Aortic dissection
- Idiopathic
- Familial Mediterranean fever

10–20?mm Hg change is equivocal. Increased pulsus paradoxus may also be seen in patients with severe dyspnea of any cause, in patients with pulmonary disease (emphysema or asthma), in obese individuals, or in patients being ventilated with a positive pressure respirator. In these patients, the paradoxical pulse is due to a marked increase in intrathoracic pressure. The cause of a paradoxical pulse in a child maintained on a ventilator after heart surgery may therefore be difficult to assess.

Diagnosis.

The specific findings depend on the underlying disease. The effects of pericarditis on the *electrocardiogram* are multiple. Low voltage of the QRS complexes results from a damping effect of pericardial fluid. Pressure on the myocardium by fluid or exudate produces a current of injury that results in mild elevation of ST segments. Generalized T-wave inversion occurs as a consequence of associated myocardial inflammation. The ST segment and T-wave changes with pericarditis are more generalized than those seen with myocardial infarction, and the ST segment elevations tend to precede the T-wave changes. *Electrical alternans* may be present and is demonstrated by a variable QRS complex amplitude. An interval when the electrocardiogram is in a transitional phase and appears to be normal may occur during the acute phase of the illness before diagnosis. In some instances, clear-cut abnormalities are never identified.

A relatively large pericardial effusion must be present to cause an enlarged cardiac shadow with the usual “water bottle” configuration on a *chest roentgenogram* (Fig. 432–1). In most instances, the lung fields are clear. With constrictive pericardial disease, the heart is relatively small and calcification may be present.

The *echocardiogram* is the most sensitive technique for evaluating the size and progression of pericardial effusions. Normally, the pericardium is closely adherent to the epicardium, and the

two layers can only be narrowly separated by the ultrasound beam. In patients with pericardial effusion, a clear, echo-free space is recorded between the epicardium and pericardium. A posterior effusion is recorded behind the left ventricular epicardium and ends at the junction of the left ventricle and left atrium. An anterior effusion will be recorded between the chest wall and the anterior right ventricular wall. The presence of both anterior and posterior effusion generally indicates a large collection of fluid. Flattening of septal motion and collapse of right ventricular outflow during diastole are signs of pericardial tamponade.

Differential Diagnosis

VIRAL AND ACUTE BENIGN PERICARDITIS.

These entities are considered synonymous because most episodes of acute benign pericarditis follow or coincide with viral illness. Viruses recognized to cause pericarditis include coxsackievirus B, influenza, echovirus, and adenovirus. The pathogenesis is unclear but may be related to a hypersensitivity reaction to the viral disease. Pericardial inflammation is not necessarily the precursor of a generalized

inflammatory process. Most cases are mild, and recovery occurs within several weeks. Only symptomatic treatment is indicated, usually with nonsteroidal anti-inflammatory agents such as indomethacin. In rare instances, the patient is severely ill, and cardiac tamponade may ensue. In addition, in some patients a chronic relapsing illness occurs. Differential diagnosis between these patients and those with collagen vascular disease may be difficult. The latter patients respond dramatically to corticosteroids or nonsteroidal anti-inflammatory agents; milder forms may be controlled with aspirin. The clinical course may vary from months to 1–2 yr, during which time patients are dependent on drug therapy for suppression of the pericarditis. Ultimately, these patients improve, and the prognosis is good.

The clinical differential diagnosis between acute pericarditis and myocarditis may be difficult; usually, each includes a component of the other. Management of these conditions is quite different: anti-inflammatory treatment and urgent response to cardiac tamponade are appropriate in the former, whereas therapy for heart failure is required in the latter. The echocardiogram can demonstrate the size of the pericardial effusion and also indicate the presence of myocardial dysfunction.

PURULENT PERICARDITIS.

This condition is most often associated with bacterial infections such as pneumonia, epiglottitis, meningitis, or osteomyelitis. Generally, signs and symptoms of the primary infection are present. Once the purulent process is established, if untreated, the course is fulminant

Figure 432-1 Roentgenograms in acute nonspecific pericarditis. *A*, Increase in cardiopericardial shadow caused by pericardial effusion. *B*, One month later after complete recovery.

and terminated by acute cardiac tamponade and death. Open pericardial drainage is required along with appropriate intravenous antibiotics. Although closed pericardial aspiration provides a sample of the exudate for diagnostic purposes and may be lifesaving in the face of severe cardiac compression, without open drainage and removal of adhesions, tamponade almost invariably recurs. Open pericardial drainage has significantly increased survival. Rarely, with infections that are identified extremely early and with pericardial fluid that is more of a transudate than an exudate, multiple pericardial taps with placement of a drain and antibiotic therapy have been successful. The most common organisms implicated in purulent pericarditis are *Staphylococcus aureus, Haemophilus influenzae* type b, and *Neisseria meningitidis*. (For antimicrobial treatment, see Chapter 166 , Chapter 178 , and Chapter 176 , respectively.) *Tuberculous pericarditis* rarely occurs in children. Extensive treatment with antituberculous chemotherapy is required (see Chapter 197). *Immune complex–mediated pericarditis* (sterile) may occur 5–7 days after the initiation of therapy for severe systemic or meningeal infection with meningococcus or *H. influenzae* type b. Therapy includes anti-inflammatory agents and pericardiocentesis if tamponade develops.

ACUTE RHEUMATIC FEVER.

Pericarditis occurs in acute rheumatic fever as a component of pancarditis (see Chapter 147.1 and Chapter 430). It is associated with acute valvulitis. Pericarditis and other manifestations of acute rheumatic pancarditis respond to therapy with steroids. Cardiac tamponade is extremely rare.

JUVENILE RHEUMATOID ARTHRITIS.

Pericarditis is a common manifestation of juvenile rheumatoid arthritis (see Chapter 145). Rarely, it may be the only manifestation and precede the onset of arthritis by months or even years. Differentiation of rheumatoid pericarditis from that seen with other collagen vascular disease, particularly lupus erythematosus, may be difficult. Treatment consists of steroids or salicylates, which may be needed on a long-term basis.

UREMIA.

Uremic pericarditis occurs only in the presence of prolonged severe renal failure and results from chemical irritation of the pericardium secondary to the metabolic abnormalities. It may culminate in cardiac tamponade or cause recurrent hypotension during hemodialysis. If adequate relief of uremic pericarditis does not occur with hemodialysis, pericardiectomy is recommended.

NEOPLASTIC DISEASE.

Neoplastic pericardial effusion is seen in patients with Hodgkin disease, lymphosarcoma, and leukemia, and it results from direct neoplastic invasion of the

pericardium. Cardiac tamponade may occur late in the course of the illness. Rarely, pericardial infiltration is the initial manifestation of neoplastic disease. Patients with malignancy may also acquire pericarditis as a result of radiation therapy to the mediastinum.

POSTPERICARDIOTOMY SYNDROME (Chapter 427).

Pericardial effusions may be seen 1–2 wk or longer after open heart surgery and in some echocardiographic series are diagnosed in 15–23% of postoperative patients. The syndrome is a nonspecific hypersensitivity reaction to trauma to the pericardium and the epicardial surface of the heart. High titers of antiheart antibodies have been reported to correlate with clinical signs of the syndrome. Patients may initially have low-grade fever, lethargy, loss of appetite, or abdominal pain. Precordial or pleural chest pain may or may not be present. A high index of suspicion should accompany any acute illness in a child within the 1st 4–6 weeks after cardiac surgery. In most children, the syndrome responds well to therapy with aspirin or other nonsteroidal anti-inflammatory agents. Corticosteroids may be needed for more severe cases, and progression to tamponade can occur if untreated. Treatment is maintained for 1–3 mo, but recurrences may be seen as long as 1 yr postoperatively and require re-institution of therapy.

432.1 Constrictive Pericarditis

In most instances, constriction occurs months or years after the initial pericarditis, but it may occasionally be an acute, rapidly progressive process. Constrictive pericarditis most often occurs without an immediately preceding illness or generalized systemic disease.

Clinical manifestations occur as a result of impaired diastolic ventricular filling, compromised myocardial contractility, and resultant depression of cardiac function. Hepatomegaly and ascites may be out of proportion to the other signs and symptoms and thus suggest chronic liver disease. Liver function studies are only mildly abnormal; careful physical examination reveals other subtle findings of constriction, including neck vein distention, narrow pulses, quiet precordium, distant heart sounds, a faint pericardial friction rub, and increased pulsus paradoxus. Typical findings become apparent gradually and may be overlooked. The auscultatory presence of an early pericardial knock and the appearance of calcification of the pericardium on chest roentgenograms are the more obvious manifestations. Protein-losing enteropathy with hypoproteinemia and lymphopenia may be seen in association with severe constriction.

Constrictive pericarditis may be difficult to distinguish from chronic restrictive cardiomyopathy (see Chapter 431.3). Impaired myocardial function occurs with both conditions. The myocardial disease of constrictive pericarditis is usually reversible with pericardiectomy. At times, a definite diagnosis can be made only by exploratory thoracotomy and direct examination of the pericardium.

Radical pericardiectomy with decortication of the pericardium over a wide area of the heart, including the systemic and pulmonary veins, is the only effective treatment of constrictive pericarditis. In most patients, surgical intervention elicits a rapid response characterized by increased cardiac output and prompt diuresis. The long-term prognosis is usually excellent.

Chapter 433 - Tumors of the Heart

Primary tumors of the heart are rare in infancy and childhood and are most often benign. Clinical manifestations depend primarily on the location of the tumor and, to a lesser extent, on the histologic type.

The most common benign cardiac tumors in children are rhabdomyomas, fibromas, and myxomas. *Rhabdomyomas* occur as single or, usually, multiple nodules embedded in chamber walls. They often remain clinically unimportant and regress with age, but they may cause mechanical obstruction, heart failure, or arrhythmias. They may be familial and are often found in association with **tuberous sclerosis**. Most rhabdomyomas are seen in infants younger than 1 yr. Incessant ventricular tachycardia in a child younger than 2 yr should raise suspicion of a small endocardial or epicardial *rhabdomyoma* or *Purkinje cell tumor. Fibromas* are usually solitary, nonencapsulated nodules located in the ventricles; they can be massive. Treatment of rhabdomyomas and fibromas depends on their location and size. Small asymptomatic tumors in the myocardial wall or ventricular septum may be observed for growth or regression. Rhabdomyomas associated with tuberous sclerosis often resolve as the child grows older. Large tumors that show signs of obstructing blood flow and those producing ventricular arrhythmias should be removed. Large and diffuse tumors may interfere with cardiac performance. Removal of large lesions is often difficult because insufficient normal myocardium may remain. Heart transplantation may be the only recourse for patients with extensive tumors.

Myxomas develop in intracavitary locations, most frequently in the left atrium (75%) and most often in females (75%). These tumors are solid, smooth, pedunculated masses (1–8?cm) that attach to the interatrial septum, protrude into the atrial chamber, and by their position relative to the mitral or tricuspid valve, cause intermittent obstruction and a clinical picture consistent with stenosis (syncope, heart failure, atrial fibrillation). A myxoma should be considered in patients with fainting spells, a positional character (supine vs erect) of the murmur, or evidence of systemic or pulmonary embolization. Atrial myxomas can also cause fever, malaise, arthralgias, and systemic emboli mimicking endocarditis, rheumatic fever, or systemic lupus erythematosus. Laboratory features include a high sedimentation rate, hematuria, and echocardiographic evidence of the tumor. Atrial myxomas may be associated with multiple pigmented skin lesions (lentiginosis), myxoid fibroadenomas of the breast, cutaneous myxomas, and adrenal pigmented nodules. Some are associated with various cutaneous and connective tissue lesions and testicular tumors or pituitary adenomas (Carney syndrome). Treatment consists of surgical excision, which must include the entire base of the tumor to prevent recurrence.

Other benign tumors include *papillomas*, which are attached to valve leaflets and may occur in neonates; *lipomas*, which are situated in ventricular walls; and *mesotheliomas*, which may involve the atrioventricular node and cause abnormalities in electrical conduction, including complete heart block.

Primary malignant cardiac tumors in children are almost exclusively *sarcomas*. These tumors are usually located in the right side of the heart, atrial septum, right atrial wall, or root of the pulmonary artery. They may extend either into the adjacent chamber and cause obstruction to blood flow or into the pericardial cavity and produce effusion or tamponade. The heart may also be involved in metastatic dissemination of a noncardiac malignancy, such as leukemia or lymphoma, or in Wilms tumor by direct extension of the tumor into the right

atrium via the inferior vena cava. Physical examination may reflect the location and size of the tumor if it interferes with blood flow. Conduction system involvement can be assessed by electrocardiography. Two-dimensional echocardiography is diagnostic and allows excellent visualization of the location and extent of the tumor. Doppler studies evaluate the extent of blood flow obstruction caused by the tumor. Cardiac catheterization may provide further information about the anatomy of the tumor and its hemodynamic effects. When indicated, surgical intervention is directed toward complete removal of the tumor, relief of obstruction, and control of any arrhythmias. The long-term outcome depends on the type of tumor, the completeness of surgical removal, and postsurgical integrity of the normal heart structures and myocardium. For tumors that are unresectable because of an inability to separate them from normal heart tissue, heart transplantation is an effective treatment. **REFERENCES**

Daniel Bernstein

Chapter 434 - Heart Failure

Heart failure occurs when the heart cannot deliver adequate cardiac output to meet the metabolic needs of the body. In the early stages of heart failure, various compensatory mechanisms are evoked to maintain normal metabolic function. When these mechanisms become ineffective, increasingly severe clinical manifestations result (Chapter 57.2).

Pathophysiology.

The heart can be viewed as a pump with an output proportional to its filling volume and inversely proportional to the resistance against which it pumps. As ventricular end-diastolic volume increases, a healthy heart increases cardiac output until a maximum is reached and cardiac output can no longer be augmented (the Frank-Starling principle; Fig. 434–1). The increased stroke volume obtained in this manner is due to stretching of myocardial fibers, but it also results in increased wall tension, which elevates myocardial oxygen consumption. Hearts working under various types of stress function along different Frank-Starling curves. Cardiac muscle with compromised intrinsic contractility requires a greater degree of dilatation to produce increased stroke volume and does not achieve the same maximal cardiac output as normal myocardium does. If a cardiac chamber is already dilated because of a lesion causing increased preload (e.g., a left-to-right shunt or valvular insufficiency), there is little room for further dilatation and augmentation of cardiac output. The presence of lesions that result in increased afterload to the ventricle (aortic or pulmonic stenosis, coarctation of the aorta) decreases cardiac performance, thereby resulting in a depressed Frank-Starling relationship. The ability of an immature heart to increase cardiac output in response to increased preload is less than that of a mature heart. Premature infants are more compromised by a left-to-right shunt than full-term infants are.

Systemic oxygen transport is calculated as the product of cardiac output and systemic oxygen content. Cardiac output can be calculated as the product of heart rate and stroke volume. The primary determinants of stroke volume are the *afterload* (pressure work), *preload* (volume work), and *contractility* (intrinsic myocardial

function). Abnormalities in heart rate can also compromise cardiac output and produce both bradyarrhythmias and tachyarrhythmias; the latter shorten the diastolic time interval for ventricular filling. Alterations in the oxygen-carrying capacity of blood (e.g., anemia or hypoxemia) also lead to a decrease in systemic oxygen transport and, if compensatory mechanisms are inadequate, can result in decreased delivery of substrate to tissues.

In some cases of heart failure, cardiac output is normal or increased, yet because of decreased systemic oxygen content (secondary to anemia) or increased oxygen demands (secondary to hyperventilation, hyperthyroidism, or hypermetabolism), an inadequate amount of oxygen is delivered to meet the body's needs. This condition, **high-output failure**, results in the development of signs and symptoms of heart failure when there is no basic abnormality in myocardial function and cardiac output is greater than normal. It is also seen with large systemic

Figure 434-1 The Frank-Starling relationship. As left ventricular end-diastolic pressure (LVED) increases, the cardiac index increases, even in the presence of congestive heart failure, until a critical level of LVED is reached. Adding an inotropic agent (digoxin) shifts the curve from I and II. (From Gersony WM, Steep CN: In Dickerman JD, Lucey JF [editors]: *Smith's The Critically Ill Child: Diagnosis and Medical Management*, 3rd ed. Philadelphia, WB Saunders, 1984.)

arteriovenous fistulas. These conditions reduce peripheral vascular resistance and cardiac afterload and increase myocardial contractility. Heart “failure” results when the demand for cardiac output exceeds the ability of the heart to respond. Chronic severe high-output failure may eventually result in a decrease in myocardial performance as the metabolic requirements of the myocardium are not met.

One major compensatory mechanism for increasing cardiac output is an increase in sympathetic tone secondary to increased adrenal secretion of circulating epinephrine and increased neural release of norepinephrine. The initial beneficial effects of sympathetic stimulation include an increase in heart rate and myocardial contractility; both serve to increase cardiac output. Because of localized vasoconstriction, blood flow may be redistributed from the cutaneous, visceral, and renal beds to the heart and brain. Prolonged increases in sympathetic stimulation can have deleterious effects as well, including hypermetabolism, increased afterload, arrhythmogenesis, increased myocardial oxygen requirements, and direct myocardial toxicity. Peripheral vasoconstriction can result in decreased renal, hepatic, and gastrointestinal tract function.

Clinical Manifestations.

The clinical manifestations depend on the degree of cardiac reserve under various conditions. A critically ill infant or child who has exhausted the compensatory mechanisms to the point that cardiac output is no longer sufficient to meet the basal metabolic needs of the body is symptomatic at rest. Other patients may be comfortable when quiet but are incapable of increasing cardiac output in response to even mild activity without experiencing significant symptoms. Conversely, it may take rather vigorous exercise to compromise cardiac function in children who have less severe heart disease. A thorough history is extremely important in making the diagnosis of heart failure and in evaluating the possible causes. Parents who observe their infant on a daily basis may not recognize subtle changes that have occurred over the course of days or weeks. Cyanosis may be considered merely “a deep coloring” and not be recognized as an abnormal finding. The history of a young infant should also focus on feeding (see Chapter 415). An infant with heart failure often takes less volume per feeding, becomes dyspneic while sucking, and may perspire profusely. Eliciting a history of fatigue in an older child requires specific questions about activity.

In children, the signs and symptoms of heart failure are often similar to those in adults and include fatigue, effort intolerance, anorexia, abdominal pain, dyspnea, and cough. However, older children and adolescents may have primarily abdominal symptoms and a surprising lack of respiratory complaints. The elevation in systemic venous pressure may be gauged by clinical assessment of jugular venous pressure and liver enlargement. Orthopnea and basilar rales are variably present; edema is usually discernible in dependent portions of the body, or anasarca may be present. Cardiomegaly is invariably noted. A gallop rhythm is common; when ventricular dilatation is advanced, the holosystolic murmur of mitral or tricuspid valve regurgitation may be heard.

In infants, heart failure may be difficult to identify. Prominent manifestations include tachypnea, feeding difficulties, poor weight gain, excessive perspiration, irritability, weak cry, and noisy, labored respirations with intercostal and subcostal retractions, as well as flaring of the alae nasi. The signs of cardiac-induced pulmonary congestion may be indistinguishable from those of bronchiolitis; wheezing is prominent. Pneumonitis with or without atelectasis is common, especially in the right middle and lower lobes; it is due to bronchial compression by the enlarged heart. Hepatomegaly usually occurs, and cardiomegaly is invariably present. In spite of pronounced tachycardia, a gallop rhythm can frequently be recognized. The other auscultatory signs are those produced by the underlying cardiac lesion. Clinical assessment of jugular venous pressure in infants may be difficult because of the shortness of the neck and the difficulty of observing a relaxed state. Edema may be generalized and usually involves the eyelids as well as the sacrum and less often the legs and feet. The differential diagnosis is age dependent (Box 434–1).

Diagnosis.

Roentgenograms of the chest show cardiac enlargement. Pulmonary vascularity is variable and depends on the cause of the heart failure. Infants and children with large left-to-right shunts have exaggeration of the pulmonary arterial vessels to the periphery of the lung fields, whereas patients with cardiomyopathy may have a relatively normal pulmonary vascular bed early in the course of disease. Fluffy perihilar pulmonary markings suggestive of venous congestion and acute pulmonary edema are seen only with more severe degrees of heart failure. Cardiac enlargement is often noted as an unexpected finding on a chest roentgenogram performed to evaluate for a possible pulmonary infection or asthma.

Chamber hypertrophy noted by *electrocardiography* may be helpful in assessing the cause of heart failure but does not establish the diagnosis. In cardiomyopathies, left or right ventricular ischemic changes may correlate well with clinical and other

noninvasive parameters of ventricular function. Low-voltage QRS morphologic characteristics with ST-T wave abnormalities may also suggest myocardial inflammatory disease but can be seen with pericarditis as well. The electrocardiogram is the best tool for evaluating rhythm disorders as a potential cause of heart failure.

Echocardiographic techniques are useful in assessing ventricular function. The most commonly used parameter is fractional

shortening, determined as the difference between end-systolic and end-diastolic diameter divided by end-diastolic diameter. Normal fractional shortening is between 28 and 40%, whereas a normal ejection fraction (which measures volume) is 55–65% as measured by angiography. The pre-ejection:ejection period ratio measured by M-mode echocardiography should be less than 40%. A long pre-ejection time with a short ejection time usually denotes myocardial failure. Doppler studies can be used to calculate cardiac output. *Arterial oxygen levels* may be decreased when ventilation-perfusion inequalities occur secondary to pulmonary edema. When heart failure is severe, respiratory or metabolic *acidosis*, or both, may be present. Infants with heart failure often display *hyponatremia* as a result of renal water retention. Total body sodium may actually be increased. Chronic diuretic treatment can decrease serum sodium levels further.

Measurement of B-type natriuretic peptide, a cardiac neurohormone released in response to increased ventricular wall tension, is elevated in adult patients whose dyspnea is due to congestive heart failure. Rapid measurement may be helpful in distinguishing heart failure from other causes of dyspnea.

Treatment.

The underlying cause of cardiac failure must be removed or alleviated if possible. If the cause is a congenital cardiac anomaly amenable to surgery, medical treatment is indicated to prepare the patient for surgery and in the immediate postoperative period while the heart is recovering from the effects of cardiopulmonary bypass. If the cause is cardiomyopathy, medical management provides temporary relief from symptoms and allows the patient to recover if the insult is reversible (e.g., myocarditis) or provides time to wait for a heart donor if heart transplantation is indicated.

GENERAL MEASURES.

Strict bed rest is rarely necessary except in extreme cases, but it is important that the child rest often and sleep adequately. Most older patients feel better sleeping in a semi-upright position. For infants with heart failure, an infant chair may be advisable. After patients begin to respond to treatment, restrictions on activities can often be modified within the context of the specific diagnosis and the patient's ability. Competitive and strenuous sports activities are usually contraindicated. For patients with severe pulmonary edema, positive pressure ventilation may be required along with other drug therapy. ß-Adrenergic agonists such as dopamine, epinephrine, and dobutamine, along with phosphodiesterase inhibitors and afterload-reducing agents (e.g., nitroprusside, captopril), may be required in an intensive care setting.

DIET.

Infants with heart failure may fail to thrive because of increased metabolic requirements and decreased caloric intake. Increasing daily calories is an important aspect of their management. Increasing the number of calories per ounce of infant formula (or supplementing breast-feeding) may be beneficial. Many infants do not tolerate an increase beyond 24 calories/oz because of diarrhea or because these formulas provide too large a solute load for compromised kidneys.

Severely ill infants may lack sufficient strength for effective sucking because of extreme fatigue, rapid respirations, and generalized weakness. In these circumstances, nasogastric feedings may be helpful. In many children with cardiac enlargement, gastroesophageal reflux is a major problem. The use of continuous drip nasogastric feedings at night, administered by pump, may improve caloric intake while decreasing problems with reflux. Occasionally, medical or surgical intervention to correct reflux is necessary (Nissen fundoplication). Continued malnutrition may be an important factor in the decision to undertake earlier surgical intervention in patients who have an operable congenital heart lesion.

The use of low sodium formulas in the routine management of infants with heart failure is not recommended because these preparations are often poorly tolerated and may exacerbate diuretic-induced hyponatremia. Human breast milk is the ideal low sodium nutritional source. The use of more potent diuretic agents allows more palatable standard formulas to be used for nutrition while controlling salt and water balance by chronic diuretic administration. Most older children can be managed with “no added salt” diets and abstinence from foods containing large amounts of sodium. A strict, extremely low sodium diet is rarely required.

DIGITALIS.

Digoxin is the digitalis glycoside used most often in pediatric patients. Its half-life of 36?hr is long enough to allow daily or twice-daily administration and short enough to limit toxic effects from overdosage. It is absorbed well by the gastrointestinal tract (60–85%), even in infants. Absorption is greater with the elixir than with tablets. An initial effect can be seen as early as 30?min after administration, and the peak effect for oral digoxin occurs at approximately 2–6?hr. When the drug is administered intravenously, the initial effect is seen in 15–30 min, and the peak effect occurs at 1–4?hr. The drug crosses the placenta, and therefore a fetus with heart failure (secondary to arrhythmia) can be treated by administering digoxin to the mother. The kidney eliminates digoxin, so dosing must be adjusted according to the patient's renal function. The rate of excretion is proportional to the glomerular filtration rate. After intravenous administration, 50–70% is excreted unchanged in the urine. The half-life of digoxin may be up to 6 days in patients with anuria because slower hepatic excretion pathways are used in these patients.

Rapid digitalization of infants and children in heart failure may be carried out intravenously. The dose depends on the patient's age (Table 434–1). The recommended schedule is to give half the total digitalizing dose immediately and the succeeding two one-quarter doses at 12?hr intervals later. The electrocardiogram

must be closely monitored and rhythm strips obtained before each of the three digitalizing doses. Digoxin should be discontinued if a new rhythm disturbance is noted. Prolongation of the P-R interval is not necessarily an indication to withhold digitalis, but a delay in administering the next dose or a reduction in the dosage should be considered, depending on the patient's clinical status. Serum digoxin determination is helpful when digitalis toxicity is suspected, although it may be less reliable in infants. ST segment or T-wave changes are commonly noted with digitalis administration and should not affect the digitalization regimen. Baseline serum electrolyte levels should be measured before and after digitalization. Hypokalemia and hypercalcemia exacerbate digitalis toxicity. Because hypokalemia is relatively common in patients receiving diuretics, potassium levels should be monitored closely in those receiving a potassium-wasting diuretic (e.g., furosemide) in combination with digitalis.

Maintenance digitalis therapy is started approximately 12?hr after full digitalization. The daily dosage is divided in two and given at 12?hr intervals for more consistent blood levels and more flexibility in case of toxicity. The dosage is one quarter of the total digitalizing dose. For patients who are initially given digitalis intravenously, maintenance digoxin can be given orally once oral feedings are tolerated. Because absorption from the gastrointestinal tract is less certain, the oral maintenance dose is usually 20–25% higher than when digoxin is used parenterally (see Table 448–1). The normal daily dose of digoxin for older children (>5 yr of age) calculated by body weight should not exceed the usual adult dose of 0.2–0.5?mg/24?hr.

Patients who are not critically ill may be given digitalis initially by the oral route, and in most instances digitalization is completed within 24?hr. When slow digitalization is desirable, for example, in the immediate postoperative period, initiation of a maintenance digoxin schedule without a previous loading dose achieves full digitalization in 7–10 days. Often, it can be carried out on an outpatient basis.

Measurement of *serum digoxin levels* is useful under several circumstances: (1) when an unknown amount of digoxin has been

TABLE 434-1 -- Dosage of Drugs Commonly Used for the Treatment of Congestive Heart Failure

Drug	Dosage
Digoxin	Premature: 20?µg/kg
Digitalization PO (1/2 initially, followed by 1/4 q8–12h 12 × 2)	Full-term neonate (up to 1 mo): 20–30?µg/kg Infant or child: 25–40?µg/kg Adolescent or adult: 0.5–1?mg in divided doses IV dose is 75% of PO dose
Digoxin maintenance	5–10?µg/kg/day divided q12h Trough serum level: 1.5–3.0 ng/mL < 6 mo old; 1–2 ng/mL >6 mo old IV dose is 75% of PO dose
Furosemide (Lasix)	
IV	1–2?mg/dose prn
PO	1–4?mg/kg/day, divided qd–qid
Bumetanide (Bumex)	
IV	0.01–0.1?mg/kg/dose
PO	0.05–0.1?mg/kg/day, divided q6–8h
Chlorothiazide (Diuril) PO	20–50?mg/kg/day, divided bid or tid
Spironolactone (Aldactone) PO	1–3?mg/kg/day, divided bid or tid
ß-Adrenergic agonists IV	
Dobutamine	2–20?µg/kg/min
Dopamine	2–30?µg/kg/min
Isoproterenol	0.01–0.5?µg/kg/min
Epinephrine	0.05–1.0?µg/kg/min
Norepinephrine	0.1–2.0?µg/kg/min
Phosphodiesterase inhibitors IV	
Amrinone	3–10?µg/kg/min
Milrinone	0.25–1.0?µg/kg/min
Afterload-reducing agents	
Captopril (Capoten) PO	

Infants	0.1–0.5?mg/kg/dose q8–12h (maximum, 4?mg/kg/day) Prematures: start at 0.01?mg/kg/dose
Children	0.1–2?mg/kg/day q8–12h (adult dose is 6.25–25?mg/dose)
Enalapril (Vasotec) PO	0.08–0.5?mg/kg/dose q12–24h (maximum, 1?mg/kg/day)
Hydralazine (Apresoline) PO	
IV or IM	0.1–0.5?mg/kg/dose (maximum, 20?mg)
PO	0.25–1.0?mg/kg/dose q6–8h (maximum, 200?mg/day)
Nitroglycerin	0.25–5?µg/kg/min
Nitroprusside (Nipride) IV	0.5–8?µg/kg/min
Prazosin	0.005–0.05?mg/kg/dose q6–8h (maximum, 0.1?mg/kg/dose)
Carvedilol	Test dose, 0.08–0.09?mg/kg 0.18?mg/kg/day bid increased to 0.4–0.7?mg/kg/day bid over 8–12 wk PO; adult maximal dose, 50?mg/day
Note: Pediatric doses based on weight should not exceed adult doses. Because recommendations may change, these doses should always be double checked. Doses may also need to be modified in any patient with renal or hepatic dysfunction.	
PO = by mouth; IV = intravenously; prn = as necessary; qd = every day; qid = three times per day; bid = twice daily.	

administered or ingested accidentally, (2) when renal function is impaired or if drug interactions are possible, (3) when questions regarding compliance are raised, and (4) when a toxic response is suspected. Blood is usually drawn immediately before a dose but at minimum 4?hr after the last dose to ensure that tissue-plasma equilibration has occurred. An appropriate blood level is approximately 2–4?ng/mL in infants and 1–2?ng/mL in older children. Exceeding these levels does not generally add to the management of heart failure significantly and only increases the risk of toxicity. In suspected toxicity, elevated serum digoxin levels are not in themselves diagnostic of toxicity but must be interpreted as an adjunct to other clinical and electrocardiographic findings (rhythm and conduction disturbances). Nausea and vomiting are less frequent in pediatric patients. Hypokalemia, hypomagnesemia, hypercalcemia, cardiac inflammation secondary to myocarditis, and prematurity may all potentiate digitalis toxicity. A cardiac arrhythmia that develops in a child who is taking digitalis may also be related to the primary cardiac disease rather than the drug. Any form of arrhythmia occurring after the institution of digitalis therapy must be considered to be drug related until proved otherwise. Succeeding doses should be withheld until the issue is resolved.

DIURETICS.

These agents interfere with reabsorption of water and sodium by the kidneys, which results in a reduction in circulating blood volume and thereby reduces pulmonary fluid overload and ventricular filling pressure. Diuretics are most often used in conjunction with digitalis therapy in patients with severe congestive heart failure.

Furosemide is the most commonly used diuretic in patients with heart failure. It inhibits the reabsorption of sodium and chloride in the distal tubules and the loop of Henle. Patients requiring acute diuresis should be given intravenous or intramuscular furosemide at an initial dose of 1–2?mg/kg, which usually results in rapid diuresis and prompt improvement in clinical status, particularly if symptoms of pulmonary congestion are present. Chronic furosemide therapy is then prescribed at a dose of 1–4?mg/kg/24?hr given between one and four times a day. Careful monitoring of electrolytes is necessary with long-term furosemide therapy because of the potential for significant loss of potassium. Potassium chloride supplementation is usually required unless the potassium-sparing diuretic spironolactone is given concomitantly. When furosemide is administered every other day, dietary potassium supplementation may be adequate to maintain normal serum potassium levels. Chronic administration of furosemide may cause contraction of the extracellular fluid compartment and result in “contraction alkalosis” (see Chapter 48.8). Diuretic-induced hyponatremia may become difficult to manage in patients with severe heart failure.

Spironolactone is an inhibitor of aldosterone and enhances potassium retention, often eliminating the need for oral potassium supplementation, which is frequently poorly tolerated. This drug is usually given orally in two to three divided doses of 2–3?mg/kg/24?hr. Combinations of spironolactone and chlorothiazide are commonly used for convenience. Adult patients have shown improved survival when this aldosterone inhibitor is included in the diuretic regimen.

Chlorothiazide is used occasionally for diuresis in children with less severe chronic heart failure. It is less immediate in action and less potent than furosemide, and it affects the reabsorption of electrolytes in the renal tubules only. The usual dose is 20–40?mg/kg/24?hr in divided doses. Potassium supplementation is often required if this agent is used alone.

AFTERLOAD-REDUCING AGENTS AND ACE INHIBITORS.

This group of drugs reduces ventricular afterload by decreasing peripheral vascular resistance and thereby improving myocardial performance. Some of these agents also decrease systemic venous tone, which significantly reduces preload. Afterload reducers are especially useful in children with heart failure secondary to cardiomyopathy and in patients with severe mitral or aortic insufficiency. They may also be effective in patients with heart failure caused by left-to-right shunts. They are not generally used in the presence of stenotic lesions of the left ventricular outflow tract. Angiotensin-converting enzyme (ACE) inhibitors may have additional beneficial effects on cardiac remodeling independent of their influence on afterload. In adult patients with dilated cardiomyopathy, the addition of an ACE inhibitor to standard medical therapy reduces both morbidity and mortality. Afterload-reducing agents and ACE inhibitors are most often used in conjunction with other anticongestive drugs such as digoxin and diuretics.

Intravenously administered agents such as *nitroprusside* should be administered only in an intensive care setting and for as short a time as possible. Nitroprusside's short intravenous half-life makes it ideal for titrating the dose in critically ill patients. Peripheral arterial vasodilation and afterload reduction are the major effects, but venodilation causing a decrease in venous return to the heart may also be beneficial. Blood pressure must be continuously monitored because sudden

hypotension can occur. Nitroprusside is contraindicated in patients with pre-existing hypotension. As the drug is metabolized, small amounts of circulating cyanide are produced and detoxified in the liver to thiocyanate, which is excreted in urine. When high doses of nitroprusside are administered for several days, toxic symptoms related to thiocyanate poisoning may occur (fatigue, nausea, disorientation, acidosis, and muscular spasm). If nitroprusside use is prolonged, blood thiocyanate levels should be monitored; values greater than 10?g/dL are consistent with clinical symptoms of toxicity. Phosphodiesterase inhibitors (see later) are also excellent afterload-reducing agents.

The orally active ACE inhibitor *captopril* produces arterial dilatation by blocking the production of angiotensin II, thereby resulting in significant afterload reduction. Venodilation and consequent preload reduction have also been reported. In addition, this agent interferes with aldosterone production and therefore also helps control salt and water retention. ACE inhibitors have additional beneficial effects on cardiac structure and function that may be independent of their effect on afterload. The oral dose is 0.3–6?mg/kg/24?hr given in two to three divided doses. Adverse reactions to captopril include hypotension and its sequelae (e.g., syncope, weakness, and dizziness). A maculopapular pruritic rash is encountered in 5–8% of patients, but the drug may be continued because the rash often disappears spontaneously with time. Neutropenia, renal toxicity, and chronic cough also occur. *Enalapril* is a longer acting ACE inhibitor that can be taken once or twice daily. Angiotensin II receptor blocking drugs have recently been introduced into management protocols for adults with heart failure; however, data on these agents in children are limited.

Intravenous nesiritide is a recombinant human brain (B-type) natriuretic peptide that has venous, arterial, and coronary vasodilatory effects. B-type natriuretic peptide is normally released by the failing ventricular myocardium. Exogenous infusion of nesiritide in adults with decompensated heart failure improves hemodynamic function and the clinical manifestations of heart failure.

a-AND ß-ADRENERGIC AGONISTS.

These drugs are usually administered in an intensive care setting, where the dose can be carefully titrated to hemodynamic response. Continuous determinations of arterial blood pressure and heart rate are performed; measuring cardiac output at the bedside with a pulmonary thermodilution (Swan-Ganz) catheter may also be helpful in assessing drug efficacy. Though extremely efficacious in the acute intensive care setting, some evidence indicates that long-term administration of adrenergic agonists may in certain cases increase morbidity and mortality in patients with heart failure.

Dopamine is a predominantly s-adrenergic receptor agonist, but it has a-adrenergic effects at higher doses. Dopamine has less chronotropic and arrhythmogenic effect than the pure ß-agonist isoproterenol does. In addition, it results in selective renal vasodilation because of its interaction with renal dopamine receptors, which is particularly useful in patients with the compromised kidney function that is often associated with low cardiac output. At a dose of 2–10?µg/kg/min, dopamine results in increased contractility with little peripheral vasoconstrictive effect. However, if the dose is increased beyond 15?µg/kg/min, its peripheral a-adrenergic effects may result in vasoconstriction.

Dobutamine, a derivative of dopamine, is useful in treating low cardiac output. It causes direct inotropic effects with a moderate reduction in peripheral vascular resistance. Dobutamine can be used as an adjunct to dopamine therapy to avoid the vasoconstrictive effects of high-dose dopamine. Dobutamine is also less likely to cause cardiac rhythm disturbances than isoproterenol is. The usual dose is 2–20?µg/kg/min.

Isoproterenol is a pure ß-adrenergic agonist that has a marked chronotropic effect; it is most effective in patients with slow heart rates and should be used with caution in those who already have significant tachycardia. Children receiving isoproterenol must be carefully monitored for arrhythmias.

Epinephrine is a mixed a- and ß-adrenergic receptor agonist that is usually reserved for patients with cardiogenic shock and low arterial blood pressure. Although epinephrine can raise blood pressure effectively, it also increases systemic vascular resistance and therefore increases the afterload against which the heart has to work.

PHOSPHODIESTERASE INHIBITORS.

Milrinone is useful in treating patients with low cardiac output who are refractory to standard therapy. It works by inhibition of phosphodiesterase, which prevents the degradation of intracellular cyclic adenosine monophosphate. Milrinone has both positive inotropic effects on the heart and significant peripheral vasodilatory effects

and has generally been used as an adjunct to dopamine or dobutamine therapy in the intensive care unit. It is given by intravenous infusion at 0.25–1?µg/kg/min, sometimes with an initial loading dose of 50?µg/kg. A major side effect is hypotension secondary to peripheral vasodilation, especially when a loading dose is used. The hypotension can generally be managed by the administration of intravenous fluids to restore adequate intravascular volume. *Amrinone*, another phosphodiesterase inhibitor, can cause thrombocytopenia; the severity appears to be related to both the rate of infusion and the duration of therapy. It is reversible when use of the drug is discontinued.

CHRONIC TREATMENT WITH ß BLOCKERS.

Studies in children and adults with dilated cardiomyopathy show that ß-adrenergic blocking agents, introduced gradually as part of a comprehensive heart failure treatment program, improve exercise tolerance, decrease hospitalizations, and reduce overall mortality. The agents most often used are metoprolol, a $ß_1$-adrenergic receptor selective antagonist, and carvedilol, an agent with both a- and ß-adrenergic receptor blocking as well as free radical scavenging effects. ß blockers are used for the chronic treatment of patients with heart failure and should not be administered when patients are still in the acute phase of heart failure (i.e., in the intensive care unit and receiving intravenous adrenergic agonist infusions). Preliminary noncontrolled studies in children show that ß blockers are well tolerated and appear to be efficacious; a multicenter controlled trial of carvedilol in pediatric patients is currently in progress.

434.1 Cardiogenic Shock (see also Chapter 57.2)

Cardiogenic shock may occur as a complication of (1) severe cardiac dysfunction before or after cardiac surgery, (2) septicemia, (3) severe burns, (4) anaphylaxis, (5) cardiomyopathy, (6) myocarditis, (7) myocardial infarction or stunning, and (8) acute central nervous system disorders. It is characterized by low cardiac output and hypotension and therefore results in inadequate tissue perfusion.

Treatment is aimed at re-institution of adequate cardiac output and peripheral perfusion to prevent the untoward effects of prolonged ischemia on vital organs, as well as management of the underlying cause. Under physiologic conditions, cardiac output is increased as a result of sympathetic discharge, which increases the heart rate. However, in the presence of cardiogenic shock with marked tachycardia, the heart rate will not increase further, and cardiac output may be reduced because of decreased diastolic filling time. Cardiac output must be increased by increasing stroke volume. If the rate of fluid administration is increased, central venous pressure and ventricular filling pressure (preload) increase, and the Frank-Starling mechanism results in increased stroke volume. Optimal filling pressure is variable and depends on a number of extracardiac factors, including ventilatory support with high positive end-expiratory

TABLE 434.1-2 -- Treatment of Cardiogenic Shock*

	Determinants of Stroke Volume		
	Preload	***Contractility***	***Afterload***
Parameters measured	CVP, PCWP, LAP, cardiac chamber size on echocardiography	CO, BP, fractional shortening on echocardiography, MV O_2 saturation	BP, peripheral perfusion, SVR
Abnormal physiologic manifestations	Low CVP, PCWP, or LAP ? CO ? BP	High CVP, PCWP, or LAP; low MV O_2 saturation ? CO ? BP	High CVP, PCWP, LAP, or SVR ? CO ? or ? BP
Treatment to improve cardiac output	Volume expansion, crystalloid, colloid, blood	ß-Adrenergic agonists, phosphodiesterase inhibitors	Afterload-reducing agents: captopril, enalapril, lisinopril

CVP = central venous pressure; PCWP = pulmonary capillary wedge pressure; LAP = left atrial pressure (measured with an indwelling LA line); CO = cardiac output (measured with a thermodilation catheter); BP = blood pressure; SVR = systemic vascular resistance (calculated from CO and mean BP); MV O_2 saturation = mixed venous oxygen saturation (measured with a central venous catheter); ? = decreased; ? = normal; ? = increased.

** The goal is to improve peripheral perfusion by increasing cardiac output: cardiac output = heart rate × stroke volume.*

pressure, peak inspiratory pressure, and intra-abdominal pressure. The increased pressure necessary to fill a relatively noncompliant ventricle should also be considered, particularly after open heart surgery. If carefully administered incremental fluid administration does not result in improved cardiac output, abnormal myocardial contractility or an abnormally high afterload, or both, must be implicated as the cause of the low cardiac output.

Myocardial contractility improves when treatment of the basic cause of shock is instituted, hypoxia is eliminated, and acidosis is corrected. However, dopamine, epinephrine, and dobutamine improve cardiac contractility, increase the heart rate, and ultimately increase cardiac output.

The use of cardiac glycosides to treat acute low cardiac output states should be avoided. Digoxin has a slower effect than catecholamines do, even with intravenous administration. In addition, adverse effects may result from larger doses, and toxicity is less predictable and depends on myocardial and serum potassium and calcium levels. It is common for patients in cardiovascular shock to have compromised renal perfusion, so administration of digoxin may result in high persistent blood levels because it is excreted by the kidneys. When digoxin is required for these patients, a lower and less frequent dosage should be used, and serum digoxin levels must be

monitored frequently.

Patients in cardiogenic shock may have a marked increase in systemic vascular resistance resulting in high afterload and poor peripheral perfusion. If the increased systemic vascular resistance is persistent and the administration of positive inotropic agents alone does not improve tissue perfusion, the use of afterload-reducing agents may be appropriate, for example, nitroprusside or milrinone in combination with dopamine. In these patients, the use of a pulmonary thermodilution catheter to measure the cardiac index and to calculate systemic vascular resistance can be indispensable in guiding therapeutic decisions.

Sequential evaluation and management of cardiovascular shock are mandatory (see Chapter 57.2). Table 434–2 outlines the general *treatment principles* for acute cardiac circulatory failure under most circumstances. Treatment of infants and children with low cardiac output after cardiac surgery depends on the nature of the operative procedure and the patient's status after surgery (see Chapter 427).

Patients with deteriorating cardiogenic shock may benefit from a left ventricular assist device (LVAD). These devices have been used successfully in children and adolescents as a bridge to cardiac transplantation. In some cases, both right and left ventricular assist is necessary (BiVAD). Once implanted, assist devices allow patients to recover sufficiently to be extubated, become ambulatory, and often leave the intensive care setting while awaiting transplantation. Patients with reversible ventricular failure, for example, those in the immediate postoperative state or those with acute myocarditis, may also benefit from extracorporeal membrane oxygenation (ECMO).

Chapter 435 - Pediatric Heart and Heart-Lung Transplantation

435.1 Pediatric Heart Transplantation

As of 1999, over 4600 heart transplants had been performed on children at 226 centers worldwide. Survival rates in children compare favorably with those in adults: 78% at 1 yr and 68% at 5 yr (Fig. 435–1). Nearly 60% of patients are alive at 10 yr. As new therapeutic regimens are introduced, the long-term outlook for pediatric heart transplant recipients continues to improve. A small, but growing number of children are surpassing 15- and 20-yr survival.

Figure 435.1-1 Survival after pediatric heart transplantation. (Data based on over 4500 patients worldwide who received heart transplants from 1982 through 1999 as listed with the Registry of the International Society for Heart and Lung Transplantation.)

Indications.

Heart transplantation is performed in infants and children with end-stage cardiomyopathy who have become refractory to medical therapy and in patients with some forms of complex congenital heart disease (e.g., hypoplastic left heart syndrome) for whom standard surgical procedures are extremely high risk. Cardiomyopathies account for over 50% of heart transplants in pediatric patients older than 1 yr, although the percentage of patients with congenital lesions (approximately 25%) is gradually increasing. In infants younger than 1 yr, congenital heart lesions represent 75% of transplants. Heart transplantation is performed in children who have previously undergone conventional surgery for congenital heart disease and in whom myocardial dysfunction later develops.

Recipient and Donor Selection.

Potential heart transplant recipients must be free of serious noncardiac medical problems such as neurologic disease, systemic infection, severe hepatic or renal disease, or severe malnutrition. Many children with ventricular dysfunction may have pulmonary hypertension and even pulmonary vascular disease, which would preclude heart transplantation. For this reason, pulmonary vascular resistance is measured at cardiac catheterization, both at rest and in response to vasodilators. Patients with fixed elevated pulmonary vascular resistance (>6–8 Wood units) are at higher risk for heart transplantation and may be considered candidates for heart-lung transplantation (see Chapter 435.2). A comprehensive social services consultation is an important component of the recipient evaluation. Because of the complex post-transplantation medical regimen, the family must have a history of compliance. Detailed informed consent must be obtained.

Donor shortage is a serious problem for both adults and children. At the national registry of transplant recipients in the United States (UNOS—the United Network for Organ Sharing), allografts are matched by ABO blood group and body weight. HLA matching is not currently feasible for heart transplantation; however, with modern immunosuppression, it may offer only minimal advantage. ABO matching may not be needed for infants. Physicians caring for a patient who may be a potential donor should contact the organ donor coordinator at a transplanting institution, who can best judge the appropriateness of organ donation and has experience in interacting with donor families. Contraindications to *organ donation* include prolonged cardiac arrest with moderate to severe cardiac dysfunction, ongoing systemic illness or infection, and pre-existing severe cardiac disease. A history of resuscitation alone or reparable congenital heart disease is not an automatic exclusion for donation. Non–heart-beating donors may provide additional hearts for those on the long waiting list.

The decision of when to place a patient on the transplant waiting list is based on many factors, including extremely poor ventricular function (left ventricular fractional shortening <10%; normal is 28–40%), poor response to medical anticongestive therapy, multiple hospitalizations for heart failure, arrhythmia, progressive deterioration in renal or hepatic function, early stages of pulmonary vascular disease, and poor nutritional status. In patients awaiting transplantation, those with poor left ventricular function (fractional shortening <15%) are usually started on a regimen of warfarin to reduce the risk of mural thrombosis and thromboembolism. Patients with cardiogenic shock unresponsive to standard pharmacologic treatment may be candidates for placement of left ventricular (LVAD) or biventricular (BiVAD) assist devices, which can stabilize hemodynamics and serve as a bridge to transplantation.

Perioperative Management.

In the classic operation, both donor and recipient hearts are excised so that the posterior portions of the atria containing the venae cavae and pulmonary veins are left intact. The aorta and pulmonary artery are divided above the level of the semilunar valves. The anterior portion of the donor's atria is then connected to the remaining posterior portion of the recipient's atria, thereby avoiding the need for delicate suturing of the venae cavae or pulmonary veins. The donor and recipient great vessels are connected via end-to-end anastomoses. A bicaval anastomosis may be used, with the donor right atrium left intact; the left atrial connection is still performed as in the classic procedure.

In the immediate postoperative period, immunosuppression is most commonly achieved with a triple-drug regimen. One protocol calls for cyclosporine, 2–10?mg/kg/24?hr; azathioprine, 2?mg/kg/24?hr; and prednisone, started at 0.6–1.0?mg/kg/24?hr and tapered to 0.2?mg/kg/24?hr over the 1st 6–12 wk, although in children, a wide range of cyclosporine doses are required to achieve

therapeutic serum levels. In many centers, an antilymphocyte preparation is added in the 1st wk, either antithymocyte globulin, monoclonal murine antihuman T-lymphocyte antibody (OKT3), or one of the humanized anti–interleukin 2 receptor antibodies. In children who do not experience significant graft rejection, steroids can be tapered to an alternate-day regimen after the 1st 6–12 mo; in many patients, steroids can be totally eliminated. In some centers, steroids are not routinely included as part of maintenance immunosuppression but are added later for the treatment of acute rejection episodes. Some centers prefer tacrolimus (FK506, Prograf) as part of the initial regimen instead of cyclosporine. Agents such as mycophenolate mofetil (CellCept) and rapamycin have gained increased use as a substitute for azathioprine.

Most pediatric heart transplant recipients can be extubated within the 1st 48?hr after transplantation and are out of bed within 3–4 days. These patients are often discharged within the 1st 2 wk after transplantation. In patients with pre-existing high-risk factors, postoperative care is considerably prolonged.

Diagnosis and Management of Acute Graft Rejection.

Post-transplantation management consists of adjusting medications to maintain a balance between the risk of rejection and the side effects of over-immunosuppression. Along with infection, acute graft rejection is a leading cause of death in adult and pediatric heart transplant recipients. The incidence of acute rejection is greatest within the 1st 3 mo after transplantation and decreases considerably thereafter. Most pediatric patients experience at least one episode of acute rejection within the 1st 2 yr after transplantation, usually at the time of weaning of one of their immunosuppressive medications. Because the symptoms of rejection can mimic many routine pediatric illnesses (e.g., gastroenteritis), the transplant center should be notified any time

that a heart transplant recipient is seen in the office or emergency room for acute illness.

Clinical manifestations of acute rejection may include fatigue, fluid retention, fever, diaphoresis, abdominal symptoms, and a gallop rhythm. The *electrocardiogram* may show reduced voltage, atrial or ventricular arrhythmias, or heart block. *Roentgenographic* examination may show an enlarged heart, effusions, or pulmonary edema. Cyclosporine modifies the clinical course of rejection; most rejection episodes occur without any detectable clinical symptoms. On *echocardiography*, indices of systolic left ventricular function usually do not deteriorate until rejection is severe. Techniques to evaluate wall thickening and left ventricular diastolic function have not fulfilled their promise as predictors of early rejection. Most transplant centers do not rely on echocardiography alone in rejection surveillance.

Myocardial biopsy is the most reliable method of monitoring patients for rejection. Biopsy specimens are taken from the right ventricular side of the interventricular septum and can be harvested relatively safely in small infants and children. In older children, myocardial biopsies may be performed as often as every 1–4 wk during the 1st 3–6 mo after transplantation. The frequency is then reduced to two or four biopsies per year unless the patient has an episode of rejection. In infants, surveillance biopsies are usually performed less often and may be as infrequent as once or twice per year. Children may have clinically unsuspected rejection episodes even 5–10 yr after transplantation; most pediatric transplant centers continue routine surveillance biopsies, albeit at less frequent intervals (every 6–12 mo).

Criteria for grading cardiac rejection are based on a system developed by the International Society for Heart and Lung Transplantation (ISHLT); these criteria take into account the degree of cellular infiltration and whether myocyte necrosis is present. ISHLT rejection grades 1A, 1B, and 2 are usually mild enough to not warrant immediate treatment, and more than 50% of these episodes may resolve spontaneously. A repeat biopsy specimen is usually obtained within several weeks. For patients with ISHLT grade 3A rejection, treatment is instituted with either intravenous methylprednisolone or a “bump and taper” of oral prednisone. Asymptomatic patients more than 3 mo post-transplant and with normal echocardiograms are often treated as outpatients. For grades 3B or 4, especially with hemodynamic instability, patients are admitted to the hospital for intravenous steroid therapy. For rejection episodes resistant to steroid therapy, additional therapeutic regimens include a repeat course of an antilymphocyte preparation (OKT3 or antithymocyte globulin), methotrexate, or total lymphoid irradiation. Patients with repeated episodes of rejection may also benefit from being switched from cyclosporine to tacrolimus (or vice versa) and from azathioprine to mycophenolate therapy. Rare patients with refractory rejection require retransplantation.

Complications of Immunosuppression

INFECTION.

Infection is one of the two leading causes of death in pediatric transplant patients (Fig. 435–2). The incidence of infection is greatest in the 1st 3 mo after transplantation when immunosuppressive doses are highest. Viral infections are the most common, especially cytomegalovirus, which accounts for as many as 25% of infectious episodes. Cytomegalovirus infection may occur as a primary infection in patients without previous exposure to the virus or as a reactivation. Severe cytomegalovirus infection can be disseminated or associated with pneumonitis and may provoke an episode of acute graft rejection or graft coronary disease (see later). Many centers use intravenous ganciclovir or cytomegalovirus immune globulin (CytoGam), or both, as prophylaxis in any patient receiving a heart from a donor who is positive for cytomegalovirus or in any recipient who has serologic evidence of previous cytomegalovirus disease. Polymerase chain reaction has markedly improved the ability to diagnose

Figure 435.1-2 Major causes of death after pediatric heart transplantation. (Data from Stanford University.)

cytomegalovirus infection and to serially monitor the efficacy of therapy. Oral preparations of ganciclovir are available for chronic therapy. Adenovirus infection may be associated with graft loss.

Most normal childhood viral illnesses are well tolerated and do not usually require special treatment. Otitis media and routine upper respiratory tract infections can be treated in the outpatient setting, although fever or symptoms that last beyond the usual course require further investigation. Gastroenteritis, especially with vomiting, can result in markedly reduced absorption of immunosuppressive medications and provoke a rejection episode. In this setting, drug levels should be closely monitored and the use of intravenous medications considered. Varicella exposure is treated with varicella immune globulin, and if the patient acquires clinical varicella infection, treatment with intravenous acyclovir attenuates the illness.

Bacterial infections are the next most frequent, with the lung being the most common site of infection (35%), followed by the blood, urinary tract, and less commonly, the sternotomy site. Other sources of post-transplantation infection include fungi (14%) and protozoa (6%). The incidence of serious infection is lower in children who can be managed without steroids.

GROWTH RETARDATION.

Patients requiring chronic steroid administration usually have decreased linear growth. Alternate-day steroid regimens generally result in improved linear growth. In patients who experience rejection when steroids are weaned, other immunosuppressants (methotrexate, total lymphoid irradiation) have shown promise as steroid-sparing agents. In children surviving longer than 5 yr after transplantation, growth is normal in 75%.

HYPERTENSION.

Hypertension is common in patients treated with cyclosporine. It is due to a combination of plasma volume expansion and defective renal sodium excretion. Corticosteroids usually potentiate cyclosporine-induced hypertension. Patients are typically managed with a combination of a diuretic and a vasodilator. Agents that work via calcium channel blockade have the additional advantage of possibly attenuating graft coronary disease (see later). The incidence of hypertension may be slightly lower in patients treated with tacrolimus.

RENAL FUNCTION.

Chronic administration of cyclosporine or tacrolimus can lead to a tubulointerstitial nephropathy in adults, but severe renal dysfunction is rare in children. Most pediatric patients gradually have an increase in serum creatinine during the 1st yr after transplantation; if renal dysfunction occurs, it usually responds to a decrease in cyclosporine dosage. Long-term patients rarely require renal transplantation.

NEUROLOGIC COMPLICATIONS.

Neurologic side effects of cyclosporine and tacrolimus include tremor, myalgias, paresthesias, and rarely, seizures. These complications can be treated with reduced doses of medication and occasionally with oral magnesium supplementation. Intracranial infections pose a significant risk, especially because some of the more

frequent signs

(nuchal rigidity) may be absent in immunosuppressed patients. The most common organisms are *Aspergillus, Cryptococcus neoformans*, and *Listeria monocytogenes*. Aseptic meningitis can be seen days or weeks after OKT3 administration and is usually self-limited.

TUMORS.

One of the serious complications limiting long-term survival in pediatric heart transplant patients is the risk of neoplastic disease. The most common is post-transplant lymphoproliferative disease (PTLD), a condition associated with Epstein-Barr virus. PTLD usually responds to a reduction in immunosuppression and acyclovir and only occasionally requires chemotherapy. Monoclonal antibodies directed against the CD20 antigen on activated lymphocytes show promise against PTLD. An increased risk of skin cancer requires that children use appropriate precautions when exposed to sunlight.

CHRONIC REJECTION.

Graft coronary artery disease (CAD) is a manifestation of chronic graft rejection that occurs in 10–20% of children. The cause is still unclear, although it is thought to be a form of immunologically mediated vessel injury. Hypercholesterolemia and hyperglycemia increase the risk of this disease. Unlike native coronary atherosclerosis, graft CAD is a diffuse process with a high degree of distal vessel involvement. Because the transplanted heart has been denervated, patients do not experience symptoms such as angina pectoris during ischemic episodes, and the initial manifestation may be cardiovascular collapse or sudden death. Most centers perform coronary angiography annually to screen for coronary abnormalities; some also perform coronary intravascular ultrasound. Several reports have suggested that dobutamine stress echocardiography is useful as a screening tool. Standard coronary artery bypass procedures are not usually helpful because of the diffuse nature of the process, although transcatheter stenting is sometimes effective for isolated lesions. For severe cases, repeat heart transplantation has been the only effective treatment. Calcium channel blockers such as diltiazem have been shown to either prevent or delay the onset of graft coronary disease in adult transplant patients. One class of cholesterol-lowering agents, the HMG-CoA (3-hydroxy-3-methyl–coenzyme A) reductase inhibitors (pravastatin, atorvastatin), may be effective in reducing the risk of both graft CAD and rejection.

OTHER COMPLICATIONS.

Corticosteroids usually result in cushingoid facies, steroid acne, and striae. Cyclosporine can cause a subtle change in facial features such as hypertrichosis and gingival hyperplasia. These cosmetic features can be particularly disturbing to adolescents and may be the motivation for noncompliance. Many of these complications are dose related and improve as immunosuppressive medications are

weaned. Osteoporosis and aseptic necrosis are additional reasons for reducing the steroid dosage as soon as possible. Diabetes and pancreatitis are rare, but serious complications.

REHABILITATION.

Despite the potential risks of immunosuppression, the prospect for rehabilitation in pediatric heart transplant recipients is excellent. Almost 95% of pediatric heart transplant recipients have no functional limitations in their daily lives. At 2 yr follow-up, almost 70% of patients do not require rehospitalization for transplant-related problems.

Pediatric heart transplant recipients can attend daycare or school and participate in noncontact competitive sports and other age-appropriate activities. Standardized measurements of ventricular function are close to normal. Because the transplanted heart is denervated, the increase in heart rate and cardiac output during exercise is slower in transplant recipients, and maximal heart rate and cardiac output responses are mildly attenuated. These subtle abnormalities are rarely noticeable by the patient.

Growth of the transplanted heart is excellent, although a mild degree of ventricular and septal hypertrophy is commonly seen, even years after transplantation. The sites of atrial and great vessel anastomoses grow without the development of obstruction. However, in neonates who undergo transplantation for hypoplastic left heart syndrome, juxtaductal aortic coarctation may recur.

As assessed by standardized psychologic testing, the psychologic adjustment to heart transplantation in children is usually good. A problem sometimes occurs with noncompliance once patients reach adolescence, and life-threatening rejection may result. Early intervention by social services counselors may be able to reduce this risk.

435.2 Heart-Lung and Lung Transplantation

More than 400 heart-lung and over 580 lung (single or double) transplants have been performed in children at approximately 60 institutions worldwide. Primary indications for heart-lung transplantation include complex congenital heart disease with pulmonary hypoplasia or Eisenmenger syndrome, primary pulmonary hypertension, congenital lung abnormalities, a_1 -antitrypsin deficiency, and end-stage parenchymal lung disease (bronchopulmonary dysplasia, chronic lung disease, interstitial fibrosis, and cystic fibrosis). Many of these patients with normal hearts may also be candidates for single- or double-lung transplantation if right ventricular function is preserved. In some patients with Eisenmenger physiology, double-lung transplantation can be performed in combination with repair of intracardiac defects. Patients with cystic fibrosis are not candidates for single-lung grafts because of the risk of infection from the diseased contralateral lung. Patients are selected according to many of the same criteria as for heart transplant recipients (see Chapter 435.1).

Post-transplant immunosuppression is achieved with a triple-drug regimen, similar to that used for heart transplantation; many groups avoid steroids during the early postoperative period to promote better airway healing. Unlike patients with isolated heart transplants, few patients with lung transplants can be weaned off steroids. Prophylaxis against infection is achieved with trimethoprim-sulfamethoxazole or aerosolized pentamidine. Ganciclovir and cytomegalovirus immune globulin prophylaxis are used as in heart transplant recipients (see Chapter 435.1).

Pulmonary rejection is common in heart-lung transplant recipients, whereas heart rejection is encountered less often than in patients with isolated heart transplants. Symptoms of lung rejection may include fever and fatigue, although many episodes are minimally symptomatic. Surveillance for rejection is performed by monitoring pulmonary function (forced vital capacity; forced expiratory volume in 1?sec [FEV_1]; forced expiratory flow, midexpiratory phase [$FEF_{25-75\%}$]), systemic arterial oxygen tension, and chest roentgenograms and by serial transbronchial biopsy. Routine biopsies are performed frequently in the 1st 3 mo and then quarterly thereafter. Because of technical limitations, biopsies are not performed in infants, who are monitored by clinical criteria alone.

Actuarial *survival* rates after heart-lung or lung transplantation in children are currently 75% at 1 yr and 45% at 5 yr; improved patient selection and postoperative management are continually improving these survival statistics. As in isolated heart transplantation, infection remains the leading cause of early death and accounts for nearly 50% of all mortality in the 1st yr after transplantation. Other causes of early morbidity and mortality include tracheal complications, pulmonary venous obstruction, donor lung dysfunction, bleeding, and acute rejection. *Obliterative bronchiolitis* (OB), a form of chronic rejection, remains a major limitation to long-term survival in a significant number of patients. OB develops in 10–50% of long-term survivors of lung transplantation. Increasing immunosuppression has markedly reduced the incidence of OB. Additional late

complications include the development of airway stenosis, accelerated graft CAD (though less common than in isolated heart transplantation), and other side effects of chronic immunosuppression (see Chapter 128 and Chapter 129).

Postoperative indices of *cardiopulmonary function* and exercise capacity show significant improvement. More than 95% of patients are without activity limitations at 2 yr follow-up. Problems of donor availability are even more severe with lung transplantation. Living related lung transplantation, in which a lobe from a parent is transplanted into a child, may partially alleviate this problem.

Daniel Bernstein

Chapter 436 - Disease of the Blood Vessels (Aneurysms and Fistulas)

436.1 Kawasaki Disease (see also Chapter 156 and Chapter 431.5)

Aneurysms of the coronary or systemic arteries may complicate Kawasaki disease and are the leading cause of morbidity in this disease (Fig. 436–1). Other than in Kawasaki disease, aneurysms are not common in children and occur most frequently in the aorta in association with coarctation of the aorta, patent ductus arteriosus, and Marfan syndrome and in intracranial vessels (see Chapter 593). They may also occur secondary to an infected embolus; infection contiguous to a blood vessel; trauma; congenital abnormalities of vessel structure, especially the medial wall; and arteritis, for example, polyarteritis nodosa and Takayasu arteritis (see Chapter 157).

436.2 Arteriovenous Fistulas

Arteriovenous fistulas may be limited to small cavernous hemangiomas or may be extensive (see Chapter 497 and Chapter 640). The most common sites in infants and children are within the cranium, in the liver, in the lung, in the extremities, and in vessels in or near the thoracic wall. These fistulas, though usually congenital, may follow trauma or be a manifestation of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease). Femoral arteriovenous fistulas are a rare complication of percutaneous femoral catheterization.

Clinical Manifestations.

Clinical symptoms occur only in association with large arteriovenous communications when arterial blood flows into a low-pressure venous system; local venous pressure is increased, and arterial flow distal to the fistula is decreased. Systemic arterial resistance falls because of the runoff of blood through the fistula. Compensatory mechanisms include tachycardia and increased stroke volume so that cardiac output rises. Total blood volume is also increased. In large fistulas, left ventricular dilatation, a widened pulse pressure, and heart failure occur. Injection of contrast material into an artery proximal to the fistula confirms the diagnosis.

Figure 436.2-1 Two-dimensional echocardiogram showing giant coronary artery aneurysms in a patient with Kawasaki disease. PA = pulmonary artery; Ao = aorta; Cor = coronary artery

Large *intracranial arteriovenous fistulas* most often occur in newborn infants in association with a *vein of Galen malformation*. The large intracranial left-to-right shunt results in heart failure secondary to the demand for high cardiac output. Patients with smaller communications may not have cardiovascular manifestations but may later be disposed to hydrocephalus (see Chapter 585.11) or seizure disorders. A newborn infant with a large symptomatic intracranial arteriovenous fistula has a grave prognosis; some survive with medical management but are subject to later complications caused by the intracranial mass. The diagnosis can often be made by auscultation of a continuous murmur over the cranium. Older children with more diffuse intracranial arteriovenous malformations may be recognized on the basis of intracranial calcification and high cardiac output without cardiac failure.

Hepatic arteriovenous fistulas may be generalized or localized in the liver and may be hemangioendotheliomas or cavernous hemangiomas. The fistula may be located between the hepatic artery and the ductus venosus or portal vein. Congenital hemorrhagic telangiectasia may also be present. Large arteriovenous fistulas are associated with increased cardiac output and heart failure. Hepatomegaly is usual, and systolic or continuous murmurs may be audible over the liver.

Peripheral arteriovenous fistulas generally involve the extremities and are associated with disfigurement, swelling of the extremity, and visible hemangiomas. Some are located in areas that result in upper airway obstruction. Because only a small minority result in large arterial runoff, cardiac failure is uncommon.

Treatment.

Medical management of heart failure is initially helpful in neonates with these conditions; with time, the size of the shunt may diminish and symptoms spontaneously regress. Hemangiomas of the liver often eventually disappear completely. Large liver hemangiomas have been treated with steroids, e-aminocaproic acid, interferon, local compression, embolization, or local irradiation; the beneficial effects of these management options are not firmly established because individual patients display marked variation in clinical course without treatment. *Catheter embolization* is rapidly becoming the treatment of choice for many patients with a symptomatic arteriovenous fistula. Embolic agents that have been used include detachable balloons, steel (Gianturco) coils, and liquid tissue adhesives (cyanoacrylate). Often, multiple procedures are necessary before flow is significantly reduced. *Surgical removal* of a large fistula may be attempted in patients with severe cardiac failure and lack of improvement with medical treatment. Surgical

treatment may be contraindicated or unsuccessful when the lesion is extensive and diffuse or is located in a position where adjoining tissue may be injured during the surgery or related procedures.

Chapter 437 - Systemic Hypertension

Systemic hypertension occurs commonly in adults and if untreated is a major risk factor for myocardial infarction, stroke, and renal failure. The prevalence of hypertension increases with age: 15% in young adults to 60% in individuals older than 65 yr. In infants and younger children, systemic hypertension is uncommon, but when present, it is usually indicative of an underlying disease process *(secondary hypertension)*. Adolescents may acquire *primary or essential hypertension* (with no underlying cause); the hypertension may track into adulthood. To increase early detection of hypertension, accurate blood pressure measurements should be part of the routine annual physical examination of all children 3 yr or older. A complete family history of hypertension should be elicited.

Accurate measurement of blood pressure requires careful attention to the comfort of the patient and is highly dependent on proper use of the equipment, whether it be a simple sphygmomanometer or a state-of-the-art automated device. Obtaining an accurate blood pressure measurement in infants is often the most difficult and time-consuming part of the physical examination. Patients of any age have some level of anxiety associated with measurement of blood pressure that may lead to a false diagnosis of hypertension. Blood pressure can be measured with the patient either seated or supine; infants may be held in the lap of a parent. Subsequent measurements taken for comparison should be obtained with the patient in the same position. Careful attention to cuff size is necessary to avoid overdiagnosis. A wide variety of bladder sizes should be available in any medical office where children are routinely cared for. The cuff should completely encircle the upper part of the arm to ensure uniform compression; the inflatable bladder should cover at least two thirds of the upper arm length and three quarters of its circumference. A cuff that is too short or narrow artificially increases blood pressure readings. Blood pressure should be obtained in all four extremities to detect coarctation of the aorta (see Chapter 420.6).

Systolic pressure is indicated by appearance of the 1st Korotkoff sound. True diastolic pressure probably lies between the muffling and the disappearance of Korotkoff sounds; muffling may be difficult to appreciate in smaller children. Palpation is useful for rapid assessment of systolic blood pressure, although the palpated pressure is generally about 10?mm Hg less than that obtained via auscultation. Doppler is an extremely

accurate method of measuring systolic blood pressure; it is less so for diastolic

pressure. Oscillometric techniques are used frequently in infants and young children, but they are susceptible to artifacts and are best for measuring mean blood pressure.

Blood pressure increases gradually with age; therefore, standard nomograms are necessary for interpretation of blood pressure values (see Figure 415–1 and Figure 415–2). If mild hypertension is found, it is imperative that the measurement be repeated twice more over a period of 6 wk. Anxiety usually decreases as the patient becomes more comfortable with the procedure; thus, repeated measurements are necessary to avoid inappropriately labeling a patient as hypertensive. Blood pressure that is consistently above the 95th percentile for age requires further evaluation. Ambulatory blood pressure monitoring may be especially useful in adolescents who have borderline hypertension in the office setting.

Etiology and Pathophysiology.

Blood pressure is the product of cardiac output and peripheral vascular resistance. An increase in either cardiac output or peripheral resistance results in an increase in blood pressure; if one of these factors increases while the other decreases, blood pressure may not increase. When hypertension is the result of another disease process, it is referred to as *secondary hypertension*. When no identifiable cause can be found, it is referred to as *primary* or *essential hypertension*. Many factors, including heredity, diet, stress, and obesity, may play a role in the development of essential hypertension.

Secondary hypertension is most common in infants and younger children. Many childhood diseases may be responsible for both acute and chronic elevation of blood pressure (Box 437–1 and Box 437–2). The most likely cause varies with age. Hypertension in the newborn is most often associated with umbilical artery catheterization and renal artery thrombosis. Hypertension during early childhood may be due to renal disease, coarctation of the aorta, endocrine disorders, or medications. In adolescents, essential hypertension becomes increasingly common. The severity of hypertension is also helpful in distinguishing secondary from primary hypertension; in general, children and adolescents with essential hypertension have blood pressure values at or only slightly above the 95th percentile for age.

Renal and renovascular hypertension accounts for the majority of children with secondary hypertension. A history of urinary tract infection is present in 25–50% of these patients and is often related to an obstructive lesion of the urinary tract. Renovascular hypertension may be associated with sodium retention and increased renin secretion. Other renal parenchymal lesions associated with hypertension are detailed in Box 437–1 and Box 437–2 . The reduced glomerular filtration rate in patients with nephritis results in salt and water retention, whereas mass lesions (cysts, solid tumors, hematoma) may impair renal perfusion and stimulate renin production by the juxtaglomerular apparatus. Both Wilms tumor and juxtaglomerular cell tumor (hemangiopericytoma) may secrete renin or other pressors without feedback control.

Lesions such as renal artery stenosis cause hypertension through stimulation of the *renin-angiotensin-aldosterone system*. Renin is a proteolytic enzyme secreted by juxtaglomerular cells that converts angiotensinogen to angiotensin I. Renin secretion is affected by afferent arteriolar perfusion pressure in the kidney, sodium concentration in plasma and tubular urine, sympathetic nervous system activation, and other factors such as prostaglandins, potassium intake, and atrial natriuretic peptides. Angiotensin I possesses little physiologic activity and is rapidly converted to angiotensin II by angiotensin-converting enzyme (ACE). This enzyme is also responsible for the metabolic degradation of vasodilating kinins. Angiotensin II is a potent vasoconstrictor and also stimulates aldosterone secretion, which leads to salt and water retention.

Several *endocrinopathies* are associated with hypertension, usually those involving the thyroid, parathyroid, and adrenal

glands. Systolic hypertension and tachycardia are common in hyperthyroidism; however, diastolic pressure is not usually elevated. Hypercalcemia, whether secondary to hyperparathyroidism or other causes, often results in mild elevation in blood pressure because of an increase in vascular tone. Adrenocortical disorders (aldosterone-secreting tumors, congenital adrenal hyperplasia, Cushing syndrome) may produce hypertension in patients with increased mineralocorticoid secretion. **Pheochromocytomas** are catecholamine-secreting tumors that give rise to hypertension because of the cardiac and peripheral vascular effects of epinephrine and norepinephrine. Children with pheochromocytoma usually have sustained rather than intermittent hypertension (see Chapter 574). Pheochromocytoma develops in approximately 5% of patients with neurofibromatosis. Altered sympathetic tone can be responsible for acute or intermittent elevation of blood pressure in children with Guillain-Barré syndrome, poliomyelitis, burns, and Stevens-Johnson syndrome. Sympathetic outflow from the central nervous system is also affected by intracranial lesions.

In adolescents, a number of *drugs of abuse, therapeutic agents*, and *toxins* may cause hypertension. Cocaine may provoke a rapid increase in blood pressure and can result in seizures or intracranial hemorrhage. Phencyclidine causes transient hypertension that may become persistent in chronic abusers. Tobacco

Low renin

Normal renin

High renin

use may also increase blood pressure. Sympathomimetic agents used as nasal decongestants, appetite suppressants, and stimulants for attention deficit disorder produce peripheral vasoconstriction and varying degrees of cardiac stimulation. Individuals vary in their susceptibility to these effects. Oral contraceptives should be suspected as a cause of hypertension in adolescent girls, although the incidence is low with the use of low-estrogen preparations. Immunosuppressant agents such as cyclosporine and tacrolimus cause hypertension in organ transplant recipients, and the effect is exacerbated by the co-administration of steroids. Blood pressure may be elevated in patients with poisoning by a heavy metal.

Essential hypertension is the most common form of hypertension in adults, and it is recognized more often in adolescents than in younger children. It is often accompanied by a strong family history. The cause of essential hypertension is likely to be multifactorial; however, obesity, genetic alterations in calcium and sodium transport, vascular smooth muscle reactivity, the renin-angiotensin system, and insulin sensitivity have been implicated in this disorder. Normotensive children of hypertensive parents may show abnormal physiologic responses that are similar to those of their parents. When subjected to stress or competitive tasks, the offspring of hypertensive adults, as a group, respond with greater increases in heart rate and blood pressure than do children of normotensive parents. Similarly, some children of hypertensive parents may excrete higher levels of urinary catecholamine metabolites or may respond to sodium loading with greater weight gain and increases in blood pressure than do those without a family history of hypertension. The abnormal responses in children with affected parents tend to be greater in the black population than in white individuals. Erythrocyte sodium transport, the free calcium concentration in platelets and leukocytes, urine kallikrein excretion, and sympathetic nervous system receptors have been investigated as other possible markers for the subsequent development of hypertension.

Categorization of essential hypertension according to the level of plasma renin activity (high, normal, low) has been useful in understanding the pathophysiology and in developing treatment regimens for adults; similar large studies have not been conducted in adolescents with primary hypertension. A large number of adult patients with essential hypertension appear to be especially sensitive to salt intake. The mechanism of salt sensitivity is not clear and may involve the chloride ion rather than sodium. A subgroup of salt-sensitive individuals appear to have impaired ability for urinary excretion of a sodium load. Atrial natriuretic peptides stimulate sodium excretion by the kidneys; their role in maintenance of normal blood pressure and development of hypertension is being investigated.

Tracking of blood pressure is the process by which individuals over time maintain their relative ranking of blood pressure with respect to their peers. Children and young adolescents with blood pressure greater than the 90th percentile for age have a threefold greater likelihood of becoming adults with hypertension than do children with blood pressure at the 50th percentile. Adolescents with essential hypertension may progress from high cardiac output and normal systemic vascular resistance to the adult pattern of normal cardiac output with elevated systemic vascular resistance. Racial differences have been noted: black adults with hypertension have greater elevations in peripheral resistance, whereas hypertensive white adults predominantly show an increase in cardiac output.

Clinical Manifestations.

Children and adolescents with essential hypertension are usually asymptomatic; the blood pressure elevation is usually mild and is detected during a routine examination or evaluation before athletic participation. These children may have mild to moderate obesity.

Children with secondary hypertension can have blood pressure elevations ranging from mild to severe. Unless the pressure has been sustained or is rising rapidly, hypertension does not usually produce symptoms. Therefore, clinical manifestations of the underlying disease, such as growth failure in children with chronic renal disease, are the most frequent reasons for detecting the hypertension. With substantial hypertension, however, headache, dizziness, epistaxis, anorexia, visual changes, and seizures may occur. Hypertensive encephalopathy is suggested by the presence of vomiting, temperature elevation, ataxia, stupor, and seizures. Regardless of the cause, end-organ (cardiac and renal) dysfunction occurs in the face of marked hypertension.

Young children and infants with unexplained heart failure or seizures should have their blood pressure measured. Such patients often cannot communicate symptoms such as headache, and their behavior may not be considered abnormal until the complications of hypertension are present. After blood pressure has been lowered, parents of hypertensive infants often comment in retrospect that their child had been increasingly irritable before the hypertension was recognized.

Diagnosis.

The diagnosis of essential hypertension is suggested by the patient's age (usually adolescent), level of blood pressure elevation (usually mild), weight (mild to moderate obesity), positive family history, and the paucity of signs and symptoms of underlying disease. It is uncommon to make this diagnosis in children younger than 10 yr. Obesity is associated with essential hypertension, but except for disorders of the adrenal cortex, patients with secondary hypertension are rarely obese. Heredity

is also a strong determinant of blood pressure; therefore, an adolescent with mild elevation of pressure and a strong family history of essential hypertension is less likely to have an underlying disease. Adolescents suspected of having essential hypertension require regular measurement of blood pressure to determine the course of the elevation over time. If blood pressure continues to rise over several weeks or months of observation, additional diagnostic studies to eliminate secondary hypertension are indicated.

The diagnosis of secondary hypertension is also suggested by the patient's age (younger), level of blood pressure elevation (varying from mild to extreme), and presence of symptoms. The history may include intermittent febrile illnesses, which might suggest recurring infection of the urinary tract (reflux nephropathy). A family history of renal disease or premature cardiovascular disease should be elicited. Careful measurement of height and weight are important because they are often less than normal in children with chronic disease. Physical examination should determine the presence of flank masses or abdominal bruits. Examination should always include palpation of pulses in all extremities and blood pressure in both arms and one leg to evaluate for possible coarctation of the aorta. Systolic blood pressure in the lower limbs of children should be 10–20?mm Hg higher than that in the upper limbs. Screening tests should include a complete blood count, urinalysis, and determination of serum electrolyte, blood urea nitrogen, serum creatinine, calcium, and uric acid levels. Urine culture should be performed even if the sediment is unremarkable. A lipid panel is indicated if the family history is suggestive or if primary hypertension is suspected. Echocardiography is helpful in assessing the chronicity of the hypertension, which if long-standing, should lead to left ventricular hypertrophy.

Renal imaging is discussed in Chapter 529 , Chapter 530 , Chapter 531 , Chapter 532 , and Chapter 533 . Renal ultrasonography provides a comparison of kidney size and a view of the anatomy of the collecting system. A radionuclide scan is helpful in distinguishing variation in perfusion or scarring of the two kidneys. Renal Doppler ultrasonography and angiography can demonstrate lesions in the main arteries or in the segmental branches; if angiography is performed, venous blood samples should be collected from both renal veins and the inferior vena cava for assay of plasma renin activity. Doppler ultrasonography may demonstrate abnormal arterial and venous blood flow.

Peripheral plasma renin activity is a useful screening test for both renovascular and renal parenchymal disease. Normal values gradually decrease with age and vary among laboratories. A suppressed value suggests excess mineralocorticoid effect, and an elevated value is associated with renal or renovascular involvement. Urinary catecholamines should be measured as well as plasma and urinary steroids. One approach to an adolescent with hypertension is summarized in Figure 437–1 . A pregnancy test may be useful in a sexually active female who is noted to be hypertensive (preeclampsia).

Figure 437-1 Algorithm for identifying children with high blood pressure (BP). Note that whenever BP measurement is stipulated, the average of at least two measurements should be used. (From Report of the second task force on blood pressure control in children—1987. Task Force on Blood Pressure Control in children. National Heart, Lung, and Blood Institute, Bethesda, Maryland. *Pediatrics* 1987;79:1. Copyright American Academy of Pediatrics 1987.)

Course and Prognosis.

The natural history of essential hypertension that is initially detected during childhood or adolescence is under investigation in several large long-term population studies. Many of these children continue to have essential hypertension as adults, although the correlation is not perfect. In adults with essential hypertension, drug therapy has been shown to be beneficial in reducing the incidence of congestive heart failure, renal failure, and stroke.

The prognosis of a child with secondary hypertension is primarily determined by the nature of the underlying disease and its responsiveness to specific therapy. Survival in patients with underlying chronic renal disease is determined by the patient's response to dialysis and the success of renal transplantation. In patients with renovascular disease, the degree of elevation in renal vein renin activity may help predict response to therapy. A discrepancy in renin secretion between the two kidneys of more than 1.5:1 suggests that the kidney producing the higher level is primarily responsible for the hypertension. In this case, surgical correction yields a high probability of marked improvement or resolution of the hypertension. The prognosis after surgical repair of coarctation of the aorta is variable and partly dependent on the age at which the correction is performed. Most patients operated on during infancy and childhood establish normal systemic blood pressure after surgery unless the coarctation recurs; patients in whom the diagnosis is made during adolescence, however, are at risk for persistently elevated pressure. The long-term outcome is favorable for neonates who experience hypertension as a complication of umbilical artery catheterization. Few of these infants require therapy beyond 12 mo of age, and most show marked improvement in renal perfusion.

Prevention.

Prevention of high blood pressure may be viewed as part of the prevention of cardiovascular disease and stroke, the leading cause of death in adults in the United States. Other risk factors for cardiovascular disease include obesity, elevated serum cholesterol levels, high dietary sodium intake, a sedentary lifestyle, and alcohol and tobacco use. Beginning in childhood and continuing through adolescence, it is especially important to discourage cigarette smoking because of the pulmonary and cardiovascular consequences. The increase in arterial wall rigidity and blood viscosity that is associated with exposure to the components of tobacco may cause or exacerbate hypertension. Population approaches to prevention of essential hypertension include a reduction in sodium intake and an increase in physical activity through school-based programs.

Treatment.

The goal of therapy for hypertension should be to reduce blood pressure below the 95th percentile for age. Both nonpharmacologic and pharmacologic approaches to treatment are useful in managing children with elevated blood pressure. Adolescents with essential hypertension are usually best managed initially with *nonpharmacologic* therapy. Intervention should focus on the risk factors that were cited as important in

prevention. Because many patients with mild elevation of pressure are obese, weight reduction may result in a 5–10?mm Hg reduction in systolic pressure. A reduction in sodium intake often lowers pressure by a similar amount. A consistent program of aerobic exercise has also been noted to reduce blood pressure in patients with mild essential hypertension. In view of these benefits and the undesirable effects of many antihypertensive drugs, a well-supervised program of nonpharmacologic therapy should be enthusiastically prescribed for most young patients with essential hypertension. Adolescents should be counseled about the adverse effects of tobacco and alcohol on blood pressure. When the patient is unable to cooperate with the nonpharmacologic approach or the reduction in blood pressure is insufficient, antihypertensive agents should be prescribed. However, adolescents who are poorly compliant with changes in lifestyle are also unlikely to be compliant with a long-term drug regimen.

For many children with secondary hypertension and for selected patients with essential hypertension, *pharmacologic* therapy is required. A number of antihypertensive drugs are available for both hypertensive emergencies and chronic therapy (Table 437–1). In response to a *hypertensive crisis*, it is important to select an agent with a rapid and predictable onset of action and to monitor blood pressure carefully as it is being reduced. Because hypertensive encephalopathy is a possible complication of hypertensive emergencies, antihypertensive agents with minimal central nervous system side effects should be chosen to avoid confusion between symptoms of disease and adverse effects of the drug. Intravenous administration is often preferred so that the fall in blood pressure can be carefully titrated. Because too rapid a reduction in blood pressure may interfere with adequate organ perfusion, a stepwise reduction in pressure should be planned. In general, the pressure should be reduced by about one third of the total planned reduction during the 1st 6?hr and the remaining amount over the following 48–72?hr.

In most *hypertensive emergencies*, the drugs of choice are intravenous labetalol or nitroprusside or sublingual nifedipine. Labetalol blocks both a- and ß-adrenergic receptors; with a single dose followed by continuous infusion, controlled reduction of blood pressure can be achieved. Similar control is possible with an infusion of nitroprusside. Nifedipine has a rapid onset of action, but its short duration of action must be anticipated. Because nifedipine is available only as a liquid within a capsule, administration to younger children has presented some difficulty. Although the drug has often been placed in the sublingual space to achieve rapid absorption, gastrointestinal absorption is also sufficiently rapid to be effective in a hypertensive crisis. Intravenous hydralazine and diazoxide, when given at intervals, are alternative agents for the management of acute hypertensive crises, but such an approach may not provide the desired gradual reduction in blood pressure. Most children with hypertensive crisis have chronic or acute renal disease; in these patients, management of blood pressure also requires careful attention to fluid balance, as well as diuresis. Intravenous furosemide is usually effective, even though glomerular filtration may be impaired.

In selecting a drug regimen for *long-term use*, an understanding of the underlying pathophysiology is helpful. Drugs with different sites and mechanisms of action are available so that therapy can be tailored to the specific pathologic condition. For example, excessive activity of the renin-angiotensin-aldosterone system may be treated effectively with a ß-blocking drug (e.g., propranolol) for suppression of renin secretion, an ACE inhibitor (e.g., captopril), or rarely, an aldosterone antagonist (e.g., spironolactone). ACE inhibitors are useful, not only in patients with high-renin hypertension that is secondary to renovascular or renal parenchymal disease but also in patients with high-renin essential hypertension. Excess angiotensin production is the probable cause of most hypertension in neonates after partial occlusion of a renal vessel by thrombus. Captopril is an effective agent in most of these patients, but it must be used with careful attention to renal function.
a-Adrenergic blocking agents (phentolamine, phenoxybenzamine) are beneficial in patients with neural crest tumors who have high circulating levels of catecholamines. In such patients, ß-blocking drugs are also needed to control the heart rate, or an agent with dual blocking action (labetalol) may be used. Sympathetic blockade with labetalol is likewise efficacious in patients who experience marked stimulation of the cardiovascular system from high doses of cocaine.

Young patients with essential hypertension who require drug therapy may be treated initially with a diuretic or a ß-blocking agent. Patients with volume-dependent hypertension usually have an adequate response to diuretics; those with high-renin, high cardiac output physiology respond best to ß blockers. If the pressure is not lowered adequately, a calcium channel blocker

TABLE 437-1 -- **Antihypertensive Drugs**

Drug	Mechanism of Action	Dosage Range	Route	Duration	Side Effects
Arterial Vasodilators					
Hydralazine	Relax arteriolar smooth muscle	0.1–0.4?mg/kg/dose	IV	2–4 hr	Tachycardia, nausea
		0.25–1?mg/kg/dose and increase to max of 200?mg/24 hr	PO	6–8 hr	Drug-induced lupus
Diazoxide	Relax smooth muscle	1–3?mg/kg/dose, max of 150?mg	IV	6–24 hr	Tachycardia, hypotension, hyperglycemi
Nitroprusside	Dilatation of arterioles and venules	0.5–8.0µg/kg/min	IV	With infusion	Thiocyanate production, rarely hypothyroidis
Minoxidil	Arteriolar dilatation	0.1–0.2?mg/kg/24 hr, max of 50?mg/24 hr	PO	12–24 hr	Hypertrichosis fluid retention
Adrenergic Blockers					
Phentolamine	a-Receptor blockade	0.05–0.1?mg/kg/dose, max of 5?mg	IV	1–2 hr	Reflex tachycardia

Phenoxybenzamine	a-Receptor blockade	0.2–1.2?mg/kg/24 hr, max single dose of 10?mg	PO	6–12 hr	Tachycardia may progress to arrhythmia
Prazosin	a-Receptor blockade	0.005–0.1?mg/kg/dose	PO	6–12 hr	First dose, orthostatic hypotension
Propranolol	ß-Receptor blockade Reduces renin release	0.01–0.1?mg/kg/dose 0.5–6.0?mg/kg/24 hr, max of 16?mg/kg/24 hr or 60?mg/24 hr	IV slow push PO	6–8 hr	Bronchospas bradycardia, vivid dreams
	Reduces renin release	0.5–6.0?mg/kg/24 hr, max of 16?mg/kg/24 hr or 60?mg/24 hr	PO		
Labetalol	a and ß blockade	0.2–1.0?mg/kg/dose, max of 20?mg dose 0.25–2.0?mg/kg/hr 1–3?mg/kg/24 hr	IV bolus IV continuous PO	With infusion 6–12 hr	Orthostasis, dizziness, bronchospas
		0.25–2.0?mg/kg/hr 1–3?mg/kg/24 hr	IV continuous PO	6–12 hr	
Clonidine	CNS a_2 -agonist	0.005–0.025?mg/kg/24 hr initially, max of 0.9?mg/24 hr	PO	6–12 hr	Sedation, constipation, rebound withdrawal, hypertension
Renin-Angiotensin Inhibitors					
Captopril	ACE inhibition	Neonates <2 mo: 0.05–0.1?mg/kg/dose up to 0.5?mg/kg/dose	PO	6–24 hr	Proteinuria, neutropenia, rash, dysgeusia, chronic cough
		Infants and children: 0.15–0.5?mg/kg/dose up to 6?mg/kg/24 hr	PO	8–12 hr	
		Older children and adolescents: 6.25–12.5?mg/dose up to 450?mg/24 hr	PO	8–12 hr	
Enalaprilat	ACE inhibition	Children: 0.005–0.010?mg/kg/dose Adults: 0.625–1.25?mg/dose	IV over 5?min	8–24 hr	Transient hypotension
Enalapril	ACE inhibition	Children: 0.2–1?mg/kg/24 hr Adolescents: 2.5–5?mg/24 hr up to 40?mg/24 hr	PO	12–24 hr	Hypotension
Calcium Channel Blockers					
Nifedipine	Calcium channel blocker	Children: 0.25–0.5?mg/kg/dose, max of 10?mg/dose and 1–2?mg/kg/24 hr	PO, SL	Repeat q 4–6h	Facial flushin tachycardia
		Adolescents: 10–30?mg (capsules) 30–120?mg qd (sustained release)	PO PO	6–8 hr 24 hr	
Diuretic Agents					
Hydrochlorothiazide	Diuresis	1–2?mg/kg/24 hr, max of 100?mg/24 hr	PO	12–24 hr	Hypokalemia, hyperuricemi shypercalcem
Furosemide	Diuresis	1?mg/kg/dose 1–2?mg/kg/dose up to 6?mg/kg/24 hr	IV PO	4–6 hr 6–12 hr	Hypokalemia, alkalosis
Bumetanide	Diuresis	0.015–0.1?mg/kg/dose, max of 10?mg/24 hr	PO	6–24 hr	Hypokalemia, hyperglycemi hyperuricemi

Note: Pediatric doses based on weight should not exceed adult doses. Because recommendations may change, these doses should always be doublechecked. Doses may also need to be modified any patient with renal or hepatic dysfunction.

ACE = angiotensin = converting enzyme; SL = sublingual.

may be added to the diuretic, and an ACE inhibitor may replace the ß blocker. Chronic use of diuretics may result in elevation of serum lipids, which may increase the risk of ischemic heart disease in adults with hypertension. Long-term investigations of this side effect in children are not available. ß-Blocking agents have also been associated with changes in serum lipids, and some studies suggest a mild reduction in exercise tolerance in patients treated with propranolol. Patients with reactive airway disease are not able to tolerate a ß-blocking agent.

Because of these side effects, ACE inhibitors and calcium channel blockers may be considered for initial therapy in an adolescent with significant hypertension. Although captopril has been used more often in the pediatric and adolescent populations, newer ACE inhibitors such as enalapril have a longer duration of action and require less frequent administration.

In patients with long-standing or poorly controlled hypertension, the underlying pathophysiology is often complex. Such patients frequently require trials of combinations of antihypertensive agents to gain control of markedly elevated or labile pressure. The basic principle of combination antihypertensive therapy is the

co-administration of drugs with different sites or mechanisms of action. Because compliance may become a problem, the drug regimen should be as simple as possible and should take advantage of longer acting agents that can be administered once or twice daily, when available. Drug calendars, parental supervision, and close patient-physician communication also help ensure compliance.

In patients with renal artery stenosis secondary to fibromuscular dysplasia, percutaneous balloon angioplasty may cure as many as 50%. Angioplasty is not successful for renal artery

stenosis because of atherosclerotic plaques. If angioplasty is unsuccessful, placement of an intravascular stent or surgery may be indicated. **REFERENCES**

Part 20 - Diseases of the Blood

Section 1 - *The Hematopoietic System*

Chapter 438 - Development of the Hematopoietic System

1599

Robin K. Ohls
Robert D. Christensen

Hematopoietic regulation in the human fetus differs markedly from that in the adult. In the adult, homeostatic maintenance is a prime function of hematopoietic regulation, whereas in the embryo and fetus, constant changes characterize all phases of hematopoiesis. During developmental erythropoiesis, the constant growth of the fetus and the resultant need to increase the red cell mass necessitates an extraordinary erythropoietic effort. In addition, the relatively low oxygen tensions but high metabolic rates of fetal tissues demand a system of oxygen delivery unique from that present in adults. During developmental granulopoiesis, the sterile intra-amniotic environment results in a low demand for neutrophils and obviates the need for maintenance of a large neutrophil reserve. Knowledge of developmental hematopoietic regulation aids the clinician in interpretation of postnatal hematologic data and results in greater appreciation for the erythropoietic and granulocytopoietic capacities and limitations of prematurely delivered neonates.

Developmental hematopoiesis occurs in three anatomic stages: mesoblastic, hepatic, and myeloid. Mesoblastic hematopoiesis occurs in extraembryonic structures, principally in the yolk sac, and begins between the 10th and 14th days of gestation. By 6–8 wk of gestation the liver replaces the yolk sac as the primary site of blood cell production, and by 10–12 wk extraembryonic hematopoiesis has essentially ceased. Hematopoiesis occurs in the liver throughout the remainder of gestation, although production begins to diminish during the second trimester as bone marrow hematopoiesis increases. The liver, however, remains the predominant hematopoietic organ through weeks 20–24 of gestation.

Each hematopoietic organ houses distinct hematopoietic populations. For example, at 18–20 wk of gestation over 85% of the cells in the fetal liver are erythroid and virtually no neutrophils are present. In contrast, at this same time, less than 40% of the cells within the bone marrow are erythroid and up to 15% are neutrophils. Moreover, the subpopulations of leukocytes present in the liver and marrow differ with gestation. Macrophages precede the presence of granulocytes in both the liver and marrow, and the ratio of macrophages to granulocytes decreases with increasing gestation. Thus, not only does the anatomic site of hematopoiesis change during gestation, but the populations of cells generated at those sites are also distinct. The mechanisms responsible for the changing anatomic sites of hematopoiesis and for the differences in blood cells produced in the yolk sac, liver, and marrow have not been determined. Regardless of gestational age or anatomic location, production of all hematopoietic tissues begins with pluripotent stem cells that are capable of both self-renewal and of clonal maturation into all blood cell lineages. Progenitor cells differentiate under the influence of hematopoietic growth factors (Table 438–1 (Table Not Available)) produced by the fetus.

Erythroid and granulocytic blood cell indices change during gestation and continue to change through the first year of life. Circulating erythrocyte and granulocyte concentrations gradually increase during the second and third trimesters (Table 438–2). In parallel with increasing erythrocyte concentrations, hematocrits increase from 30–40% during the second trimester and continue to increase to term values over the latter part of the third trimester. Term hematocrits range from 50–63% (with variability due to delayed clamping of the umbilical cord and the sampling site). Unlike the blood concentrations of erythrocytes and neutrophils, platelet concentrations remain constant from 18 wk of gestation through term, with a range of 150,000–450,000/μL.

Mean cell volumes generally are inversely proportional to gestation and to the life span of the cell. The mean cell volume (MCV) of erythrocytes is more than 180?fL in the embryo, falls to around 130 by mid gestation, then decreases to 115?fL by 40 wk of gestation (see Table 438–2). Mean platelet volumes (MPV) range from 10–12 fL at birth and can sometimes be helpful in determining whether diminished platelet counts are primarily caused by decreased production (small MPV) or increased destruction (normal to large MPV).

Granulocytopoiesis.

The process whereby hematopoiesis moves from the yolk sac to the liver to the marrow is not a simple transfer in location, because the type of cells produced at each anatomic site is unique. For instance, the human yolk sac does not engage in neutrophil production. Also, the human fetal liver produces few, if any, neutrophils. Those few neutrophils seen in human fetal liver are not arranged in hematopoietic islands like the developing hepatic erythroblasts but are widely separated, generally

near vessels, suggesting they were made elsewhere and carried to the liver by the circulation. Similarly, no neutrophil production occurs in the human fetal spleen. The neutrophils seen within the spleen are mostly mature and evenly dispersed, suggesting that, like the neutrophils in the fetal liver, they were produced elsewhere and carried to that site by the circulation.

Neutrophils are first observed in the human fetus about 5 wk post conception as small clusters of cells around the aorta. These cells contain myeloperoxidase, and they mature into cells with segmented nuclei, but other similarities between them and the neutrophils of adults have not been reported. The fetal bone marrow space begins to develop around the eighth week post conception. From 8–10 wk the bone marrow space enlarges, but no neutrophils are apparent in this space until 10.5 wk. These first marrow neutrophils have round nuclei, contain myeloperoxidase, and express cell surface characteristics of myeloblasts and promyelocytes. From 14 wk through term the

* *Including normoblasts.*

most common cell type found in the fetal bone marrow space is the neutrophil.

In children and adults neutrophils and macrophages originate from a common progenitor cell. It is not clear whether this is the case in the fetus, because neutrophils and macrophages appear at different times and in different anatomic locations. Macrophages first appear in the yolk sac, liver, lung, and brain, before the bone marrow cavity is formed.

The mechanisms regulating fetal granulocyte production have not been well defined. Granulocyte colony-stimulating factor (G-CSF) and macrophage colony-stimulating factor (M-CSF) are likely to be involved, as they are in adults, because both are expressed in the developing fetal bone as early as 6 wk post conception and both are expressed in the fetal liver as early as 8 wk. Granulocyte-macrophage colony-stimulating factor (GM-CSF) and stem cell factor (SCF) are also distributed widely in human fetal tissues. However, no changes in mRNA expression of any of these factors, or of their specific receptors, or in the concentrations of proteins (as judged by immunohistochemical staining) appear to be the signal for fetal production of neutrophils or macrophages. The precise signals have not yet been identified.

Few neutrophils are found in the circulation until the third trimester. Forester and Daffos observed a mean circulating neutrophil count of 190/mm^3 (range, 0–490/mm^3, mode concentration of zero) in fetuses of 20 wk gestation. Although mature neutrophils are scarce, progenitor cells, with the capacity to generate neutrophil clones, are relatively abundant in fetal blood. When these fetal progenitor cells are cultured in vitro in the presence of recombinant G-CSF they undergo maturation into large colonies of neutrophils. The physiologic role of G-CSF includes upregulation of neutrophil production, and this appears to be the case for the fetus and neonate as well as for adults. Thus, the low quantities of circulating and storage neutrophils in the mid-trimester human fetus may be due in part to low production of G-CSF. Monocytes isolated from the blood of

adults produce G-CSF when stimulated with a variety of inflammatory mediators such as bacterial lipopolysaccharide (LPS) or interleukin-1 (IL-1). In contrast, monocytes isolated from the umbilical cord blood of preterm infants, and from the liver and bone marrow of aborted fetuses up to 24 wk gestation, generate only small quantities (10–100 times less per cell) of G-CSF protein and mRNA after LPS or IL-1 stimulation. Despite this low capacity to generate G-CSF, G-CSF receptors on the surface of neutrophils of newborn infants are equal in number and affinity to those on adult neutrophils.

In the fetus, the actions of G-CSF, M-CSF, GM-CSF, and SCF are not limited to hematopoiesis. Receptors for each of these factors are located in distinct areas of the fetal central nervous system and gastrointestinal tract, where their patterns of expression change with development. Important developmental roles exist for these

factors beyond those known for hematopoiesis.

Thrombopoiesis.

The marrow megakaryocyte compartment can be conceptualized as consisting of two pools of cells: *megakaryocyte progenitors* and *megakaryocytes*. The megakaryocyte progenitor pool can be identified by two methods: a culture system, in which the progenitors are identified by their ability to form colonies of megakaryocytes, and immunologic staining methods, which allow characterization on the basis of the specific antigens. Megakaryocytes are identified by their morphologic characteristics, as they undergo endoreduplication that results in large cells with polyploid nuclei.

Megakaryocyte progenitors can be subcategorized into two populations: burst-forming unit-megakaryocytes (BFU-MK), which are primitive megakaryocyte progenitors, and colony-forming unit-megakaryocytes (CFU-MK), which are more differentiated cells. BFU-MK produce large multifocal colonies containing 50 or more megakaryocytes, whereas CFU-MK generate smaller (3–50 cells/colony) unifocal colonies. BFU-MK express CD34 but not HLA-DR, whereas CFU-MK express CD34 and HLA-DR. The colonies generated by BFU-MK of fetal origin contain significantly more megakaryocytes than do those of adult origin and on that basis are thought to represent somewhat more primitive cells.

Megakaryocytes, unlike megakaryocyte progenitors, do not have the capacity to generate clones. Rather, they undergo maturation, progressing from small mononuclear cells to large polyploid cells. The modal megakaryocyte ploidy in normal adult marrow is 16N. In the fetus and neonate, modal ploidy is lower and megakaryocyte size is smaller. However, umbilical cord blood has a higher concentration of megakaryocytes than does adult blood. Large megakaryocytes generate more platelets than do small megakaryocytes; thus, it is assumed that megakaryocytes of neonates produce fewer platelets than do their adult counterparts.

The processes of platelet production and release from megakaryocytes are not well understood. It has been speculated that small buds, proplatelets, are formed on marrow megakaryocytes and that these are released from the marrow as platelets. An alternate possibility is that platelets are principally released from megakaryocytes in the lungs, as a consequence of shear forces. That theory is supported by the observation that megakaryocytes are abundant in the lungs.

Thrombopoietin (TPO) is the physiologic regulator of platelet production and acts as a potent stimulator of all stages of megakaryocyte growth and development. The gene that encodes TPO is located on the long arm of human chromosome 3, and TPO-mRNA is expressed primarily in liver and kidney and, to a lesser extent, in bone marrow stroma. TPO is a primary, but not exclusive, regulator of platelet production. TPO also stimulates the proliferation and survival of not only megakaryotic progenitors but also erythroid, myeloid, and multipotential progenitors. Phase I/II human trials have demonstrated that rTPO acts as a stimulator of platelet production in nonthrombocytopenic adults and in patients with chemotherapy-induced thrombocytopenia. Recombinant TPO clearly supports the growth of megakaryocytic colonies of neonates and children. Progenitors of preterm neonates are more sensitive to rTPO than are progenitors of term neonates. However, nothing is known about the benefits and risks of rTPO administration in neonates and children.

Erythropoiesis.

Erythropoiesis in utero is controlled by erythroid growth factors produced solely by the fetus. Erythropoietin (EPO) does not cross the placenta in humans; therefore, stimulation of maternal EPO production does not result in stimulation of fetal red cell production. Moreover, suppression of maternal erythropoiesis by hypertransfusion does not suppress fetal erythropoiesis.

It is unclear whether the same mechanism of erythropoietic regulation defining adult erythropoiesis exists in the fetus or in the infant born prematurely. The production of red blood cells is governed by a variety of growth factors produced by a variety of accessory cells such as macrophages, lymphocytes, and stromal cells. These cells and cell products make up the erythropoietic microenvironment and stimulate maturation, growth, and differentiation at various stages of red blood cell production. Of all the factors stimulating erythropoiesis, none plays a more important regulatory role than EPO. EPO is a 30–39 kd glycoprotein that binds to specific receptors on the surface of erythroid precursors and stimulates their differentiation and clonal maturation into mature erythrocytes. The regulation of EPO gene expression involves an oxygen-sensing mechanism, and both hypoxia and anemia stimulate erythropoiesis by stimulating mRNA transcription and EPO production. EPO mRNA production is regulated by *cis*-acting elements in the promoter and 3' enhancer regions that are responsive to hypoxia. Two factors, hepatic nuclear factor 4 (HNF-4) and hypoxic inducible factor (HIF-1), exhibit transcriptional activation for EPO and other hypoxia-inducible genes. HNF-4 has been shown to bind specifically to the EPO promoter and enhancer regions of the gene and is expressed in kidney, liver, and Hep3B cells. HIF-1 is a basic helix-loop-helix transcription factor composed of HIF-1a and HIF-1ß subunits that bind to *cis*-acting hypoxia-response elements and induce EPO transcription. HIF-1 is expressed in many cells and is involved in upregulation of a variety of hypoxically regulated proteins. HIF-1a appears to be constitutively expressed and rapidly degraded under normoxic conditions. HIF-1 regulation occurs through DNA binding and protein stabilization. RNA stability may be dependent on the ubiquitin proteasome degradation system; inhibition of this system leads to increased HIF-1 and increased EPO, even under normoxic conditions. In mouse models exposed to hypoxia, HIF-1a mRNA concentrations do not change significantly. It is unknown whether HIF-1a operates in the same fashion in the fetus. Moreover, the development of these transcription activating factors in the fetus and premature infant remains to be determined. There is some evidence that HIF-1 is present to varying degrees during fetal development.

The fetal liver produces EPO during the first and second trimesters, principally by cells of monocyte/macrophage origin. At some time during the third trimester and the first few weeks of life, the anatomic site of EPO production shifts from the liver to the kidney. The specific stimulus for the shift of EPO production from liver to kidney is unknown but might involve the significant changes in arterial oxygen tension that occur at birth. In animal models, the sensitivity of the hepatic hypoxia-sensing mechanism appears decreased compared with renal sensitivity. The liver also appears to require more prolonged hypoxia to achieve an EPO response. Although EPO mRNA and protein can be found in the human fetal kidney, it is not known whether this production is biologically relevant. However, it appears that

renal production of EPO is not essential for normal fetal erythropoiesis, as evidenced by the normal serum EPO concentrations and normal hematocrits of anephric fetuses.

Studies of bone marrow cells in tissue culture have added to our understanding of how erythroid precursors respond to growth factors. When bone marrow cells are placed in semi-solid media culture systems for 5–7 days, the EPO-sensitive precursors, termed colony-forming units–erythroid (CFU-E) clonally mature into clusters containing 30–100 normoblasts. Erythroid-specific progenitors that are less well differentiated than CFU-E, hence more primitive cells, are termed burst-forming units–erythroid (BFU-E). Twelve to 14 days after these cells are placed in culture, BFU-E develop into large clusters of normoblasts, each containing 200–10,000 cells. BFU-E from human fetuses respond in a slightly different fashion than BFU-E isolated from adults. Specifically, BFU-E of fetal origin generally develop into erythroid clones more rapidly and generally develop substantially more normoblasts than do BFU-E of adult origin. Moreover, BFU-E from adult bone marrow require a combination of EPO plus another factor such as IL-3 or GM-CSF to clonally mature, whereas many fetal BFU-E mature in the presence of EPO alone.

Hemoglobin.

The combustion essential to life requires that tissues receive a constant supply of oxygen. The evolutionary development of oxygen-carrying proteins, the hemoglobins, increased the ability of blood to transport oxygen. Furthermore, the combination of oxygen with hemoglobin and its dissociation from it are accomplished without expenditure of metabolic energy.

Hemoglobin is a complex protein consisting of iron-containing heme groups and the protein moiety globin. A dynamic interaction between heme and globin gives hemoglobin its unique properties in the reversible transport of oxygen. The hemoglobin molecule is a tetramer made up of two pairs of polypeptide chains, each chain having a heme group attached. The polypeptide chains of various hemoglobins are of chemically different types. The major hemoglobin of a normal adult (Hb A) is made up of one pair of alpha (a) and one pair of beta (ß) polypeptide chains and represented as a_2 $ß_2$. The major hemoglobin in the fetus (Hb F) is represented by a_2 $?_2$.

The various globin chains differ in both the number and sequence of amino acids, and their synthesis is directed by separate genes (Fig. 438–1). Two sets of genes for the a chains are located on human chromosome 16. Two pairs of alleles provide the genetic information for the structure of the a chain. ß, ?, d genes are closely linked on chromosome 11.

Within the RBCs of an embryo, fetus, child, and adult, six different hemoglobins may normally be detected: the embryonic hemoglobins, Gower-1, Gower-2, and Portland; the fetal hemoglobin, Hb F; and the adult hemoglobins, Hb A and Hb A_2 . The electrophoretic mobilities of hemoglobins vary with their chemical structures. The time of appearance and quantitative relationships among the hemoglobins are determined by complex developmental processes (Fig. 438–2).

Embryonic Hemoglobins.

The blood of early human embryos contains two slowly migrating hemoglobins, Gower-1 and Gower-2, and Hb Portland, which has Hb F–like mobility. The zeta (?) chains of Hb Portland and Gower-1 are structurally quite similar to a chains. Both Gower hemoglobins contain a unique type of polypeptide chain, the epsilon (e) chain. Hb Gower-1 has the structure $?_2$ e_2 , and Gower-2, a_2 e_2 . Hb Portland has the structure $?_2$ $?_2$. In embryos of 4–8 wk gestation, the Gower hemoglobins predominate, but by the 3rd mo they have disappeared.

Fetal Hemoglobin.

Hb F contains ? polypeptide chains in place of the ß chains of Hb A. Its resistance to denaturation by strong alkali is the basis for determining the presence of fetal RBCs in the maternal circulation (the Kleihauer-Betke test). After the

Figure 438-1 Organization of the globin genes. The bottom line reflects the scale in kilobases. Transcription of mRNA takes place from the 5' to the 3' end. The upper segment represents the beta-like globin genes on chromosome 11, and the lower segment the alpha-like genes on chromosome 16. Regions of the gene that code for primary globin proteins are shown as shaded segments, and regions that code for pseudogenes ("?," nonexpressed remnants) are shown as hatched segments. The composition of embryonic, fetal, and adult hemoglobins is listed. a = alpha; ß = beta; ? = gamma; d = delta; e = epsilon; ? = zeta.

8th gestational wk, Hb F is the predominant hemoglobin; at 24 wk gestation it constitutes 90% of the total hemoglobin. During the 3rd trimester, a gradual decline occurs, so that at birth Hb F averages 70% of the total. Synthesis of Hb F decreases rapidly postnatally, and by 6–12 mo of age only a trace is present. Less than 2.0% can be detected by alkali denaturation in older children and adults. Hb F is heterogeneous because of two types of ? chains, whose synthesis is directed by two sets of genes. The chains differ at position 136 in the presence of either a glycine (G?) or an alanine (A?) residue. In newborns, the relative proportion or ratio of G? to A? chain is 3:1.

Adult Hemoglobins.

Some Hb A (a_2 $ß_2$) can be detected in even the smallest embryos. Accordingly, it is possible as early as 16–20 wk gestation to make a prenatal diagnosis of major ß-chain hemoglobinopathies, such as thalassemia major. Prenatal diagnosis is based on techniques that examine the rates of synthesis of ß chains or the structure of newly synthesized ß chains. Earlier diagnosis is possible using molecular biology techniques and sampling of chorionic villus tissue or amniotic fluid if DNA structural defects are a cause of the hemoglobinopathies. Similarly, gene deletion disorders such as the a-thalassemias are detectable by the same method.

By the 24th wk of gestation, 5–10% of Hb A is present. A steady increase follows, so that at term, Hb A averages 30%. By 6–12 mo of age, the normal Hb A pattern

appears. The minor Hb A component Hb A_2 contains delta (d) chains and has the structure a_2 d_2 . It is seen only when significant amounts of Hb A are also present. At birth, less than 1.0% of Hb A_2 is seen, but by 12 mo of age the normal level of 2.0–3.4% is attained. Throughout life, the normal ratio of Hb A to A_2 is about 30:1.

Normal Relationships Among the Hemoglobins.

During fetal life and early childhood, the rates of synthesis of ? and ß chains and the

---

Figure 438-2 Changes in hemoglobin tetramers (*top*) and in globin subunits (*bottom*) during human development from embryo to early infancy. (From Polin RA, Fox WW: Fetal and Neonatal Physiology, 2nd ed. Philadelphia, WB Saunders, 1998, p 1769.)

amounts of Hb A and Hb F are inversely related. This relationship has been attributed to a "switch mechanism" similar to genetic regulatory mechanisms in bacteria, but the genetic, biologic, and developmental processes that direct a switchover from predominantly ?-chain synthesis in utero to predominantly ß-chain synthesis after birth are unclear. It is not certain whether the mechanisms involve selective genetic inhibition or facilitation. The increase in the a_1 /a_2 globin ratio occurring after 36 wk gestation corresponds with a rapid decline in ?-globin synthesis, suggesting that these changes could be regulated by a coordinated molecular mechanism. Differential selection and amplified production of RBC precursors derived from BFU-E result in considerable Hb F production. This may be the basis for the increased levels of Hb F that occur in many hypoproliferative or hemolytic anemias. Alternative explanations involve more basic genetic regulators in the DNA sequences that flank the hemoglobin gene complexes.

Alterations of the Hemoglobins by Disease.

Because hemoglobins containing e chains are normally present only very early in intrauterine life, they are largely of theoretical interest. Small amounts of the Gower hemoglobins have been detectable in a few newborns with 13/15-trisomy. Increased levels of Hb Portland have been found in cord blood of stillborn infants with homozygous a-thalassemia.

Hb F levels may be influenced by various factors. Because the Hb F level is elevated during the 1st year of life, knowledge of its normal decline is important (Fig. 438–3). In persons heterozygous for ß-thalassemia (ß-thalassemia trait), postpartum decrease of Hb F is retarded; about 50% of such persons have elevated levels of Hb F (>2.0%) in later life. In homozygous thalassemia (Cooley anemia) and in hereditary persistence of Hb F, large amounts of Hb F are characteristically found. In patients with major ß-chain hemoglobinopathies (e.g., Hb SS, SC), Hb F is usually increased, particularly during childhood. Preterm infants treated with human recombinant EPO may increase Hb F production during active erythropoiesis. Finally, moderate elevations of Hb F may occur in many diseases accompanied by hematologic stress, such as hemolytic anemias, leukemia, and aplastic anemia, because of a minor population of RBCs that contains increased amounts of Hb F. Tetramers of ? chains (?$_4$ or Hb Barts) or ß chains (ß$_4$, Hb H) may be found in a-thalassemia syndromes.

The normal adult level of Hb A_2 (2.0–3.4%) is seldom altered. Levels of Hb A_2 exceeding 3.4% are found in most persons with the ß-thalassemia trait and in those with megaloblastic anemias secondary to vitamin B_{12} and folic acid deficiency. Decreased HbA_2 levels are found in those with iron-deficiency anemia and a-thalassemia.

Metabolism of the RBC.

The nucleated RBCs in bone marrow participate in various metabolic functions, including active protein synthesis. After extrusion of the nucleus, much of this metabolic ability is lost, including the ability to synthesize proteins. Loss of the nucleus makes the RBC a better vessel for oxygen transport, but it imposes on the RBC a finite life span, because the cell cannot replace or repair its vital enzymatic proteins. Mature RBCs contain more than 40 enzymes. Many of these are essential for cellular viability, but genetically determined deficiencies of others, such as catalase, do not interfere with normal survival.

Mature RBCs are not metabolically inert. They have no mitochondria, however, and adenosine triphosphate (ATP) generation cannot occur by oxidative phosphorylation in Krebs' cycle reactions. Rather, glucose is taken up and lactic acid produced mostly by anaerobic glycolysis (Embden-Meyerhof pathway);

Figure 438-3 Pre- and postnatal changes in the percentage of total hemoglobin represented by fetal hemoglobin (Hb F) (*shaded area*). The triangles represent postnatal production by reticulocytes in premature infants, and the dots represent cord blood and postnatal reticulocyte production in term infants. (From Brown MS: Fetal and neonatal erythropoiesis. In Stockman JA, Pochedly C [editors]: *Developmental and Neonatal Hematology*. New York, Raven Press, 1988.)

about 10% of glucose is metabolized oxidatively through the pentose phosphate pathway. At least five functions for ATP generated by glucose metabolism are essential to normal cell viability:

1. Maintenance of electrolyte gradients. The principal intracellular cation of RBCs is potassium, whereas that in plasma is sodium. Reversal of the constant tendency for sodium to enter the RBCs and concomitantly for potassium to leak out, with preservation of normal ionic gradients, is accomplished by an energy (ATP)-dependent membrane mechanism, the cation pump. When the cation pump fails, sodium and water enter the RBCs, causing them to swell and ultimately to hemolyze. Energy is also used to maintain low intracellular levels of calcium ion.
2. Initiation of energy production. ATP is required for the initial reaction of glycolysis involving phosphorylation of glucose to glucose-6-phosphate.
3. Maintenance of RBC membrane and shape. Energy is required to maintain the

complex phospholipid structure of the RBC membrane. Maintenance of the biconcave shape is probably also energy dependent.

4. Maintenance of heme iron in the reduced (ferrous) form. Oxidative potentials within the RBC may cause oxidation of the iron of hemoglobin. Hemoglobin containing ferric iron (methemoglobin) is ineffective in oxygen transport. Moreover, if peroxides and other oxidant substances are not inactivated, hemoglobin may be denatured and precipitated. Cells containing such denatured hemoglobin (Heinz bodies) are rapidly removed from the circulation. Protection of RBCs from the effects of oxidation ultimately depends on NADPH and NADH. These compounds are continually regenerated by activities of the glycolytic pathway and pentose shunt. In many genetically determined deficiencies of glycolytic and pentose pathway enzymes, hemolytic states occur because the energy necessary to perform these vital functions cannot be generated.
5. Maintenance of the levels of organic phosphates such as 2,3-diphosphoglycerate and ATP within the RBCs. These compounds interact with hemoglobin and have profound effects on oxygen affinity.

Red Cell Life Span.

The differences in physical properties of RBCs derived from term and preterm infants may in part account for the decreased life span of neonatal RBCs within the circulation. The average life span for a neonatal RBC is 60–90 days, approximately one half to two thirds that of an adult RBC. When neonatal RBCs are transfused into adults, they exhibit a shortened life span, owing to alterations intrinsic to the neonatal RBC. In contrast, cells transfused from adult donors appear to survive normally in newborns. With increasing degrees of prematurity, remarkably shorter red cell life spans (35 to 50 days) are found. The shortened red cell life span of the preterm and term neonate may be explained by some of the characteristics specific to newborn cells: a rapid decline in intracellular enzyme activity and ATP, loss of membrane surface area by internalization of membrane lipids, decreased levels of intracellular carnitine, increased susceptibility of membrane lipids and protein to peroxidation, and increased mechanical fragility due to increased membrane deformability.

Chapter 439 - The Anemias

Bertil Glader

Anemia is defined as a reduction of the red blood cell (RBC) volume or hemoglobin concentration below the range of values occurring in healthy persons. Table 439–1 lists the means and ranges for hemoglobin and hematocrit values by age groups of well-nourished children. There may be racial differences in hemoglobin levels. Black children have levels about 0.5?g/dL lower than those of white and Asian children of comparable age

TABLE 439-1 -- Hematologic Values During Infancy a

Age	Hemoglobin (g/dL)		Hematocrit (%)		Reticulocytes (%)	MCV (fL)	Leukocytes (WBC/mm^3)	
	Mean	***Range***	***Mean***	***Range***	***Mean***	***Lowest***	***Mean***	***Range***
Cord blood	16.8	13.7–20.1	55	45–65	5.0	110	18,000	(9,000–30,000)
2 wk	16.5	13.0–20.0	50	42–66	1.0		12,000	(5,000–21,000)
3 mo	12.0	9.5–14.5	36	31–41	1.0		12,000	(6,000–18,000)
6 mo–6 yr	12.0	10.5–14.0	37	33–42	1.0	70–74	10,000	(6,000–15,000)
7–12 yr	13.0	11.0–16.0	38	34–40	1.0	76–80	8,000	(4,500–13,500)
Adult								
Female	14	12.0–16.0	42	37–47	1.6	80	7,500	(5,000–10,000)
Male	16	14.0–18.0	47	42–52		80		

fL = femtoliters; MCV = mean corpuscular volume; WBC = white blood cells.

* *Relatively wide range.*

and socioeconomic status, possibly, in part, because of the high incidence of a-thalassemia in blacks.

Although a reduction in the amount of circulating hemoglobin decreases the oxygen-carrying capacity of the blood, few clinical disturbances occur until the hemoglobin level falls below 7–8?g/dL. Below this level, pallor becomes evident in the skin and mucous membranes. Physiologic adjustments to anemia include increased cardiac output, increased oxygen extraction (increased arteriovenous oxygen difference), and a shunting of blood flow toward vital organs and tissues. In addition, the concentration of 2,3-diphosphoglycerate (2,3-DPG) increases within the RBC. The resultant “shift to the right” of the oxygen dissociation curve, reducing the affinity of hemoglobin for oxygen, results in more complete transfer of oxygen to the tissues. The same shift in the oxygen dissociation curve may also occur at high altitude. When moderately severe anemia develops slowly, surprisingly few symptoms or objective findings may be evident. However, weakness, tachypnea, shortness of breath on exertion, tachycardia, cardiac dilatation, and congestive heart failure ultimately result from increasingly severe anemia, regardless of its cause.

When oxygen delivery by RBCs to tissues is decreased, various mechanisms, including expanded cardiac output, increased production of 2,3-DPG in RBCs, and higher levels of erythropoietin (EPO), help the body compensate for the deficiency. RBC production by the bone marrow in response to EPO may expand severalfold and thereby compensate for mild to moderate reductions in RBC life span. However, in some anemias, the bone marrow loses its usual capacity for sustained production and expansion of the RBC mass; and, in these instances, absolute reticulocyte numbers in the peripheral blood are decreased. If the normal reticulocyte percentage of total RBCs during most of childhood is about 1.0% and the expected RBC count is approximately 4.0×10^6 /mm^3 , then the normal absolute reticulocyte number should be about 40,000/mm^3 . In the presence of anemia, EPO production and the absolute number of reticulocytes should rise. A normal or low absolute number or percentage of reticulocytes in response to anemia indicates relative bone marrow failure or ineffective erythropoiesis (e.g., megaloblastic anemia, thalassemia). Measurement of the serum transferrin receptor (TfR) level or examination of the bone marrow distinguishes between these possibilities, because TfR is elevated in ineffective erythropoiesis (or in iron deficiency) and is decreased in marrow RBC hypoproliferation.

Anemia is not a specific entity but results from many underlying pathologic processes. RBC size changes with age; and before an anemia can be specifically characterized with respect to RBC size, normal developmental changes in the mean corpuscular volume (MCV) should be understood (see Table 439–1). It is important that pediatricians recognize the MCV variations in childhood because many laboratories use only adult normal values, which differ considerably. For every child with significant anemia, it is essential also to review the appearance of RBCs on a peripheral blood smear (Fig. 439–1). Specific morphologic features may point to the underlying diagnosis. In addition, the presence of polychromatophilia, which generally correlates the degree of reticulocytosis, indicates that the marrow is able to respond to RBC loss or destruction.

A useful approach to assessing the common causes of anemia in children is summarized next and in Box 439–1 .

Is anemia associated with other hematologic abnormalities?

The presence of thrombocytopenia, abnormalities in white blood cell numbers, or the presence of abnormal leukocytes often indicates bone marrow failure caused by aplastic anemia, leukemia, or other malignant marrow disease. These disorders can be differentiated by careful review of screening hematologic studies and close attention to the medical history and physical examination.

Box 439-1. Approach to Common Causes of Anemia in Children

Is anemia associated with other hematologic abnormalities?

If yes, consider

Aplastic anemia

Leukemia

Other bone marrow replacement disorders

Is anemia associated with reticulocytosis?

If yes, usually a consequence of bleeding or ongoing hemolysis

Is there associated hyperbilirubinemia or increased serum lactate dehydrogenase

If yes, usually due to hemolysis

Is there associated hyperbilirubinemia or increased serum lactate dehydrogenase

If yes, usually due to hemolysis

Review of peripheral blood smear

Spherocytes (hereditary spherocytosis, autoimmune hemolytic anemia, Wilson disease)

Sickle forms (sickle cell disease, sickle-ß-thalassemia)

Target cells (hemoglobin SC disease)

Hypochromic RBC, nucleated RBC (homozygous ß-thalassemia, Hgb E-ß-thalassemia)

Microangiopathy (hemolytic-uremic syndrome, thrombotic thrombocytopenia

Bite cells/blister cells (G6PD deficiency)

Is anemia associated with a lower than appropriate reticulocyte response?

If yes, assess red blood cell size

Are red blood cells microcytic?

If yes, usually due to defect in hemoglobin synthesis

Iron deficiency

a or ß-Thalassemia trait

Hemoglobin E disorders (AE, EE)

Lead poisons

Are red blood cells macrocytic?

If yes, is there neutrophil hypersegmentation (megaloblastic changes)?

Are red blood cells macrocytic?

If yes, is there neutrophil hypersegmentation (megaloblastic changes)?

If yes, consider

Folate deficiency, vitamin B12 deficiency, inborn errors of metabolism

If no, consider

Diamond-Blackfan anemia

Congenital dyserythropoietic anemia

Pearson syndrome

Are red blood cells normocytic?

If yes, consider

Anemia of chronic disease usually (associated comorbid conditions)

Anemia of renal disease (renal failure)

Transient erythroblastopenia of childhood

Anemia associated with hypothyroidism

Is anemia associated with reticulocytosis?

In anemic children with an appropriate reticulocyte response, the cause usually is a consequence of bleeding or ongoing hemolysis. The most characteristic feature of hemolysis is reticulocytosis with indirect hyperbilirubinemia and often increased serum lactate dehydrogenase as indicators of accelerated erythrocyte destruction. Review of the peripheral blood smear to identify abnormal RBC morphology (e.g., spherocytes, sickle forms, microangiopathy) often is helpful in ascertaining the cause of hemolysis.

Is anemia associated with reticulocytopenia?

Anemia in children with a less than appropriate reticulocyte response reflects an impairment of normal erythropoiesis, and it is in this group that analysis of red blood cell size (MCV) is particularly useful.

Are red blood cells microcytic?

Almost all children in this category have defects in hemoglobin synthesis from either iron deficiency, thalassemia trait, hemoglobin E disorders, or hemoglobin C. Thalassemia trait disorders and other hemoglobinopathies are considered in patients of Mediterranean, Near Eastern, African, or Asian background. A distinguishing feature of thalassemia trait conditions and hemoglobin E is that the RBC count often is elevated above normal despite the presence of a mild anemia and microcytosis; this is in marked contrast to iron deficiency, in which the RBC count decreases along with the reduced hemoglobin and MCV.

Are red blood cells macrocytic?

The anemia in these children is sometimes megaloblastic, a result of impaired DNA synthesis and nuclear development, and the formation of other blood cells is also affected. The peripheral blood smear in megaloblastic anemias contains large macrovalocytes, and frequently there is nuclear hypersegmentation of the neutrophils. The varied major causes of megaloblastic anemia include folate deficiency, Vitamin B_{12} deficiency, and rare inborn errors of metabolism. However, not all macrocytic anemias are megaloblastic, and one such important condition in children is Diamond-Blackfan anemia.

Are red blood cells normocytic?

Normocytic anemia, low reticulocyte count, and normal bilirubin levels characterize a large number of anemias. The anemia of chronic disease usually is normocytic, although rarely it may be slightly microcytic. In these cases there usually is clinical evidence of associated inflammatory disease or chronic illness. The anemia of renal failure is normocytic and is caused by reduced erythropoietin production. Invariably, there is clinical and laboratory evidence of significant renal disease. The most common cause of acquired pure red cell aplasia seen in pediatrics is transient erythroblastopenia of childhood, a normocytic anemia.

Section 2 - *Anemias of Inadequate Production*

Bertil Glader

Chapter 440 - Congenital Hypoplastic Anemia (Diamond-Blackfan Anemia)

This rare condition usually becomes symptomatic in early infancy, often with pallor in the neonatal period, but occasionally may first be noted later in childhood. Over 90% of cases are recognized in the 1st year of life, and the average age of diagnosis is 3 mo. The most characteristic hematologic features are macrocytic anemia, reticulocytopenia, and a deficiency or absence of red blood cell (RBC) precursors in an otherwise normally cellular bone marrow.

Etiology.

The majority of cases are sporadic, although dominant or recessive patterns of inheritance are indicated by familial occurrence in about 15% of patients. The primary defects are in the erythroid progenitor cells, where there is an intrinsic defect that results in increased apoptosis (programmed cell death). High levels of erythropoietin (EPO) are present in serum and urine, although a search for mutations in the EPO receptor gene has been negative. In about 25% of sporadic and inherited cases there are mutations in a gene (*DBA1*) for a ribosomal protein S19, mapped to chromosome 19q13. A second gene for Diamond-Blackfan anemia has been linked to chromosome 8p,

and most likely other genetic abnormalities will be identified. A unifying etiology for this disorder and the significance of these genetic alterations is being defined.

Clinical Manifestations.

Although hematopoiesis is generally adequate in fetal life, some affected infants appear pale in the first days after birth; rarely, hydrops fetalis occurs. Profound anemia usually becomes evident by 2–6 mo of age, occasionally somewhat later. Over 50% of affected children have congenital anomalies, including short stature, craniofacial deformities, or defects of the upper extremities, including triphalangeal thumbs. The abnormalities are diverse, with no specific pattern emerging in the majority of those affected.

Laboratory Findings.

The RBCs are almost always macrocytic for age, but there is no hypersegmentation of neutrophils or other peripheral blood characteristics of megaloblastic anemia. Folic acid and vitamin B_{12} levels are normal. Chemical evaluation of RBCs reveals an enzyme pattern similar to a “fetal” RBC population, and there is also elevated fetal hemoglobin (Hb F) and increased expression of “i” antigen. Erythrocyte adenosine deaminase (ADA) activity is increased in most patients with this disorder, a finding that helps distinguish congenital RBC aplasia from acquired transient erythroblastopenia of childhood (see Chapter 442). Also, because elevated ADA activity is not a fetal RBC feature, measurement of this enzyme is helpful in diagnosing Diamond-Blackfan anemia in very young infants. Thrombocytosis or thrombocytopenia and occasionally neutropenia may also be present initially. Reticulocytes are characteristically very low despite severe anemia. RBC precursors in the marrow are markedly reduced in most patients, but other marrow elements are usually normal. Serum iron levels are elevated. Bone marrow chromosome studies are normal and, unlike in Fanconi anemia, there is no increase in chromosomal breaks when lymphocytes are stressed with alkylating agents.

Differential Diagnosis.

Congenital hypoplastic anemia must be differentiated from other anemias with low reticulocyte counts. The anemia of hemolytic disease of the newborn can have a protracted course and, on occasion, be associated with markedly reduced erythropoiesis. This usually terminates spontaneously at 5–8 wk of age. Aplastic anemic crises characterized by reticulocytopenia and by decreased numbers of RBC precursors, frequently caused by parvovirus B19 infections, may complicate various types of chronic hemolytic disease, but usually after the first several months of life (see Chapter 442). Infection with parvovirus B19 in utero may also cause pure RBC aplasia in infancy, even with hydrops fetalis at birth. The absence of parvovirus B19 detected by polymerase chain reaction (PCR) is now considered an essential feature in establishing the diagnosis of Diamond-Blackfan anemia in young infants. The syndrome of transient erythroblastopenia of childhood (see Chapter 442) may be differentiated from Diamond-Blackfan syndrome by its relatively late onset (although it may occasionally develop in infants younger than 6 mo). In very young infants whose RBCs have many fetal features, a determination of elevated erythrocyte ADA activity is particularly useful because this increased enzyme activity is not a characteristic of fetal RBCs.

Treatment.

Corticosteroid therapy is beneficial in three fourths of patients who respond initially. The mechanism of its effect is unknown. Prednisone in three divided doses totaling 2?mg/kg/24?hr is used as an initial trial. An increase in RBC precursors appears in bone marrow 1–3 wk after therapy is begun, and this is followed by peripheral

reticulocytosis. The hemoglobin may reach normal levels in 4–6 wk, although there is much variability in the rate of response. Once the hemoglobin concentration is clearly increasing, the dose of corticosteroid may be reduced gradually by tapering divided doses and then by eliminating all except a single, lowest effective daily dose. This dose should then be doubled, used on alternate days, and tapered still further while maintaining the hemoglobin level at 9?g/dL or above. In some patients, very small amounts of prednisone, as low as 2.5?mg twice a week, may be sufficient to sustain adequate erythropoiesis. Overall, 60% of children with Diamond-Blackfan anemia initially started on steroids stop taking the drug. This occurs because of unacceptable steroid side effects or evolution of steroid refractoriness at acceptable steroid doses, or, occasionally, there is spontaneous remission of anemia.

In patients who do not respond to corticosteroid therapy, transfusions at intervals of 4–8 wk are necessary to sustain normal growth and activities. Chelation therapy for iron overload with deferoxamine administered subcutaneously through a portable pump should be started when excess iron accumulation is reflected by serum ferritin levels exceeding 1,500?mg/dL, but preferably after 5 yr of age, because the medication may interfere with normal growth. An oral iron chelator, deferiprone (L1), is in clinical trials and may be almost as effective as deferoxamine; however, there is some controversy related to possible hepatic toxicity. The drug is licensed for use in Canada, the United Kingdom, and India but not in the United States. Other therapies, including androgens, cyclosporine, cyclophosphamide, antithymocyte globulin (ATG), high-dose intravenous immunoglobulin, high-dose methylprednisolone, EPO, and interleukin-3 have not had a consistent beneficial effect and may have a high incidence of side effects. Splenectomy may decrease the need for transfusion if hypersplenism or isoimmunization develops. Stem cell transplantation from a related histocompatible donor has a role in children who do not respond to corticosteroids and who have demonstrated a several-year need for RBC transfusions. The survival results for matched-related donors have been very encouraging, but the responses have been much inferior with the use of partially mismatched siblings or matched unrelated donors.

Prognosis.

Median survival is probably more than 40 yr of age, although definitive data are lacking. The outlook is best in those who respond to corticosteroid therapy. About half of patients are long-term responders. In the others, survival depends on transfusions. Some children in each group may eventually have spontaneous remissions (about 20%), and most of these remissions occur in the first decade. In children who are regularly transfused, total body iron increases and hemosiderosis ensues. The liver and spleen may enlarge, and secondary hypersplenism with leukopenia and thrombocytopenia can occur. The complications of chronic transfusions in Diamond-Blackfan anemia are similar to those in ß-thalassemia major, and prevention and treatment of iron overload should be equally aggressive in both groups of transfused patients (see Chapter 454). Diamond-Blackfan anemia may be a premalignant syndrome, with acute leukemia (usually myeloid) and myelodysplasia occurring in a small fraction (less than 5%) of patients. Solid tumor malignancies also have been reported, in particular osteosarcoma. Other significant causes of death include complications associated with stem cell transplantation, steroid therapy (opportunistic infections), and iron overload.

Chapter 441 - Pearson Marrow-Pancreas Syndrome

This form of congenital hypoplastic anemia may be initially confused with Diamond-Blackfan syndrome or transient erythroblastopenia of childhood. The marrow failure usually appears in the neonatal period and is characterized by a macrocytic anemia and, occasionally, neutropenia and thrombocytopenia. The level of hemoglobin F is elevated. There are

vacuolated erythroblasts and myeloblasts in the marrow. This disorder is considered a unique variant of congenital sideroblastic anemia because the marrow also contains ringed sideroblasts. Other clinical features are failure to thrive, pancreatic fibrosis with insulin-dependent diabetes and exocrine pancreatic deficiency, muscle and neurologic impairment, and, frequently, early death. This multiorgan disorder is caused by mitochondrial DNA deletions, with heterogeneity in different tissues and between patients. The heterogeneity accounts for the variable clinical picture, and a change in proportions of mtDNA types in tissues over time may result in spontaneous improvement of red blood cell hypoproliferation. Therapy includes transfusions of red blood cells as needed. Filgrastim (granulocyte colony-stimulating factor) may reverse episodes of severe neutropenia.

Chapter 442 - Acquired Pure Red Blood Cell Anemias

Transient Erythroblastopenia of Childhood (TEC).

This is the most common acquired red cell aplasia occurring in children, and it is more common than congenital hypoplastic anemia. This syndrome of severe, transient hypoplastic anemia occurs mainly in previously healthy children between 6 mo and 3 yr of age, with most older than 12 mo at onset. The cause of this decrease in red blood cell (RBC) production is a transient immunologic suppression of erythropoiesis. It frequently follows a viral illness, although a specific virus has not been identified. Parvovirus B19 infections, which may cause hypoplasia in children with chronic hemolytic anemia (see Chapter 461), are not responsible for TEC. Reticulocytes and bone marrow erythroid precursors are markedly decreased, although examination of the bone marrow rarely is needed to make the diagnosis. Some degree of neutropenia may occur in up to 20% of cases while platelet numbers are normal or elevated. Just as is the case in iron-deficiency anemia and other RBC hypoplasias, thrombocytosis presumably is caused by increased erythropoietin, which is known to have some homology with thrombopoietin. Mean corpuscular volume (MCV) is characteristically normal for age, and fetal hemoglobin (Hb F) levels are normal before the recovery phase. RBC adenosine deaminase (ADA) levels are normal in this disorder, whereas they are elevated in a majority of children with congenital hypoplastic anemia. Differentiation from the latter disease sometimes may be difficult, but differences in age at onset and in age-related MCV, Hb F, and ADA usually are helpful. The peak occurrence of TEC coincides with that of iron-deficiency anemia in infants receiving milk as their main caloric source; however, differences in MCV clearly distinguish these two disorders.

Virtually all children recover within 1–2 mo. RBC transfusions may be necessary for severe anemia in the absence of signs of early recovery. The anemia develops slowly, and marked symptoms usually develop only with severe anemia. Corticosteroid therapy is of no value in this disorder. Any child with presumed TEC who requires more than one transfusion should be re-evaluated for another possible diagnosis. In rare instances a prolonged case of apparent TEC may be caused by parvovirus-induced RBC aplasia occurring in children with congenital or acquired immunodeficiencies.

Red Cell Aplasia Associated with Chronic Hemolysis.

Parvovirus B19 is the best documented viral cause of RBC aplasia; it is the cause of fifth disease or erythema infectiosum (see Chapter 230). The virus is particularly

infective and cytotoxic for erythroid progenitor cells in the marrow, interacting specifically with the RBC P antigen as a receptor. Characteristic nuclear inclusions in erythroblasts and giant pronormoblasts can be seen with light microscopy of bone marrow. Hemophagocytosis may also be seen in the marrow, perhaps accounting for the occasional granulocytopenia and thrombocytopenia. Because infection with this virus is usually transient, with recovery occurring in less than 2 wk, anemia is not present or not noticed in otherwise normal children, in whom the life span of peripheral RBCs is 110–120 days. However, in patients with hemolysis, such as that caused by hereditary spherocytosis or sickle cell disease, in whom RBC life span is much shorter, a brief cessation of erythropoiesis from parvovirus infection may cause severe anemia, the “aplastic crisis” occurring in these diseases. Recovery from moderate to severe anemia is usually spontaneous, heralded by a wave of nucleated RBCs and subsequent reticulocytosis in the peripheral blood. An RBC transfusion occasionally is necessary for marked symptoms caused by anemia. In children with chronic hemolysis this “aplastic crisis” from parvovirus usually occurs only once.

Red Cell Aplasia Associated with Immunodeficiency.

Rarely, persistence of parvovirus infection may occur in patients unable to mount an adequate antibody response to the virus, as in children with congenital immunodeficiency diseases, those being treated with immunosuppressive agents, and those with AIDS. The resultant pure RBC aplasia may be severe and affected children are often thought to have TEC. This type of RBC aplasia differs from TEC in that there is no spontaneous recovery and more than one transfusion needs to be given. The diagnosis of parvovirus infection is made by detecting viral particles (by polymerase chain reaction) because the usual serologic responses are impaired in these immunodeficient children. The viral infection in these chronically infected patients may be treated with high doses of intravenous immunoglobulin (IVIG), which contains neutralizing antibody to parvovirus.

Red Cell Aplasia with Miscarriage and Hydrops Fetalis.

Different clinical manifestations of infection with this virus and destruction of erythroid precursors occur with infections in utero, in which there is increased fetal wastage in the first and second trimesters, and infants may be born with hydrops fetalis and viremia. The presence of persistent congenital parvovirus infection needs to be detected by examination of bone marrow DNA because immunologic tolerance to the virus may prevent the usual development of specific antibodies.

Other Red Cell Aplasias in Children.

Adult types of red cell aplasia are usually chronic antibody mediated and frequently associated with disorders such as chronic lymphocytic leukemia, lymphoma, thymoma, and systemic lupus erythematosus. This chronic antibody–mediated type of RBC aplasia is extremely rare in childhood. Certain drugs such as chloramphenicol also can inhibit erythropoiesis in a dose-dependent manner. Reticulocytopenia, erythroid hypoplasia, and vacuolated pronormoblasts in the marrow are reversible effects of this drug; and these effects are distinct from the idiosyncratic and rare development of severe aplastic anemia in recipients of chloramphenicol.

Chapter 443 - Anemia of Chronic Disorders (ACD) and Renal Disease

Anemia complicates a number of chronic systemic diseases associated with infection, inflammation, or tissue breakdown. Examples include chronic pyogenic infections, such as bronchiectasis and osteomyelitis, and chronic inflammatory processes, such as rheumatoid arthritis, systemic lupus erythematosus, and ulcerative colitis. Despite diverse underlying causes, the erythroid abnormalities are similar, although incompletely understood. The red blood cell (RBC) life span is mildly decreased, but this increased hemolysis is not the major problem. More importantly, there is a relative failure of bone marrow to respond adequately to the anemia. This impaired erythropoietic response is believed to be related to three factors. First, iron is trapped in the macrophages and is unavailable for hemoglobin synthesis. Second, despite slightly increased erythropoietin (EPO) levels the morphologically appearing normal marrow is unable to increase erythropoiesis. Third, although EPO production is slightly increased, this elevation is inadequate for the degree of anemia. A unifying explanation for the abnormal findings in this type of anemia is not available. One hypothesis is that the underlying medical conditions cause the release of interleukin-1 (IL-1) and tumor necrosis factor (TNF), and, subsequently, these cytokines lead to the production of interferon-beta (IFN-ß) and interferon-gamma (IFN-?). This hypothesis is supported by the observation that IFN-ß and IFN-? given to experimental animals causes a disorder similar to the anemia of chronic disease. The specific stimulant of increased TNF and IL-1 production in these patients has not been identified.

The anemia seen in chronic renal disease shares some features with the anemia of chronic disease, such as a mild degree of hemolysis. However, the major component of this anemia is decreased EPO production owing to damage of the renal cells producing this cytokine.

Clinical Manifestations.

Although the important symptoms and signs are those of the underlying disease, the quality of life may be affected by the mild to moderate anemia that is present.

Laboratory Findings.

Hemoglobin concentrations are usually 6–9?g/dL. The anemia is usually normochromic and normocytic, although occasionally some patients may have modest hypochromia and microcytosis. Absolute reticulocyte counts are normal or low, and leukocytosis is common. The serum iron level is low, without the increase in total iron-binding capacity (serum transferrin) that occurs in iron deficiency. This pattern of low serum iron and low to normal iron-binding protein (serum transferrin) is a regular and valuable diagnostic feature. The serum ferritin level may be elevated. The bone marrow has normal cellularity; the RBC precursors are low to adequate, marrow hemosiderin may be increased, and granulocytic hyperplasia may be present. A frequent clinical challenge is to identify concomitant iron deficiency in patients with an inflammatory disease. Measurement of the TfR/ferritin ratio may be useful, because it is elevated when iron deficiency is present (see Chapter 439). A trial of iron therapy also may help resolve the issue, although there may be no response when inflammation caused by the primary disease persists.

Treatment and Prognosis.

Because these anemias are secondary to other disease processes, they do not respond to iron or hematinics unless there is concomitant deficiency. Transfusions raise the hemoglobin concentration temporarily, but they are rarely indicated. If the underlying systemic disease can be controlled, the anemia will resolve. Recombinant human EPO can increase the hemoglobin level and improve activity and the sense of well-being in patients with cancer and end-stage renal failure and in those with anemia of chronic inflammation. Treatment with iron is usually necessary for an optimal EPO effect.

Chapter 444 - Congenital Dyserythropoietic Anemias (CDA)

These are a class of hemolytic disorders characterized by unique morphologic abnormalities in marrow erythroblasts (multinuclearity, abnormal nuclear fragments, and intrachromatin bridges between cells). Glycosylation of membrane proteins is impaired, and there also is an accumulation of red blood cell (RBC) glycolipids. The cause of both of these abnormalities is thought to be a deficiency of *N*-acetyl-glucosaminyltransferase II, an RBC enzyme responsible for membrane protein glycosylation. Clinically, these disorders are characterized by variable degrees of anemia despite the fact that there is increased marrow erythroid activity (i.e., ineffective erythropoiesis). CDA has been reported in newborn infants with hydrops fetalis. Three major types of CDA (types I, II, and III) have been defined.

Type I CDA is a rare autosomal recessive disorder in which the onset of macrocytic anemia and/or jaundice may be noted at any age, although the majority of cases are first recognized in the neonatal period. The reticulocyte count is less than expected for the degree of anemia. White blood cells and platelets are normal. Indirect bilirubin levels are slightly elevated, haptoglobin levels are low, and transferrin is saturated with iron (serum iron level approximates the total iron-binding capacity concentration). The marrow exhibits erythroid hyperplasia, shown by megaloblastic erythroblasts in the absence of vitamin B_{12} or folate deficiency. A small number of erythroblasts manifest dyserythropoietic features with interchromatin bridges between cells. *Treatment* of this disorder has been unsuccessful with the usual hematinics (vitamins and steroids), but some improvement has been achieved with interferon alfa. Although splenomegaly is common, splenectomy is not helpful. The most important long-term complication is hemosiderosis caused by increased intestinal absorption of iron and ineffective erythropoiesis. The gene for CDA type I has been mapped to chromosome 15q15.1.

Type II CDA is an autosomal recessive disorder, and it is the most common variant of CDA. The gene for CDA II has been mapped to chromosome 20q11.2. The clinical and laboratory features are similar to those seen in type I CDA; however, the magnitude of anemia usually is greater. Many more late marrow erythroblasts (up to 50%) may be abnormal, as manifested by binuclearity, multinuclearity, and abnormal lobulation. The pathognomonic findings in CDA type II are that the patient's RBCs are lysed by acidified serum. The combination of erythroblast multinuclearity and the sensitivity of circulating RBC to lysis by acidified normal serum is the reason that type II CDA is known by the acronym HEMPAS (*h*ereditary *e*rythroblastic *m*ultinuclearity with a *p*ositive *a*cidified *s*erum test). Patients with severe anemia require blood transfusions. Iron overload occurs from both transfusions and increased intestinal absorption (even in untransfused patients), and in select patients iron chelation therapy should be considered.

Type III CDA, the least common type of CDA, is a mild-to-moderate macrocytic anemia. Transfusions usually are not required. In contrast to CDA types I and II, this disorder is inherited as an autosomal dominant defect. A characteristic bone marrow feature is erythroid hyperplasia, with many multinucleated erythroblasts containing up to 12 nuclei. The gene for type III CDA has been mapped to chromosome 15q21.

Chapter 445 - Physiologic Anemia of Infancy

Normal newborn infants have higher hemoglobin and hematocrit levels with larger red blood cells (RBCs) than older children and adults. Within the first week of life, a progressive decline in hemoglobin level begins and persists for 6–8 wk. The result of this decline is generally referred to as **physiologic anemia of infancy**. Several factors are operative. With the onset of respirations at birth, considerably more oxygen is available for binding to hemoglobin and the hemoglobin-oxygen saturation increases from 50–95% or more. Furthermore, the normal developmental switch from fetal to adult hemoglobin synthesis actively replaces high oxygen affinity fetal hemoglobin with lower oxygen affinity adult hemoglobin, which can deliver a greater fraction of hemoglobin-bound oxygen to the tissues. Therefore, immediately after birth the increase in blood oxygen content and tissue oxygen delivery downregulates erythropoietin (EPO) production and, as a consequence, erythropoiesis is suppressed. In the absence of erythropoiesis, hemoglobin levels decrease because there is no replacement of aged RBCs as they are normally removed from the circulation. Iron from degraded RBCs is stored for future hemoglobin synthesis. The hemoglobin concentration continues to decrease until tissue oxygen needs are greater than oxygen delivery. Normally, this point is reached between 8–12 wk of age when the hemoglobin concentration is 9–11?g/dL. As hypoxia is detected by renal or hepatic oxygen sensors, EPO production increases and erythropoiesis resumes. The iron previously stored in reticuloendothelial tissues can then be used for hemoglobin synthesis. The supply of stored iron is sufficient for hemoglobin synthesis, even in the absence of dietary iron intake, until approximately 20 wk of age. This “anemia” should be viewed as a physiologic adaptation to extrauterine life, reflecting the excess capability for oxygen delivery relative to tissue oxygen requirements. There is no hematologic problem, and no therapy is required.

Premature infants also develop a physiologic anemia. The same factors are operative as in term infants, but they are exaggerated. The decline in hemoglobin level is both more extreme and more rapid. Minimal hemoglobin levels of 7–9?g/dL commonly occur by 3–6 wk of age, and in very small premature infants levels may be even lower (see Chapter 86). The cause of this anemia is multifaceted. An important component in the first few weeks of life is blood loss as a result of sampling for the many laboratory tests necessary to stabilize the clinical status of these infants, particularly those with cardiorespiratory problems. The erythropoietic response to anemia is also suboptimal, a significant problem because demands on erythropoiesis are heightened by the short survival of the RBCs of premature infants (40–60 days instead of 120 days as in adults) and the rapid expansion of the RBC mass that accompanies growth. The basis for suboptimal erythropoiesis in prematurity appears to be inadequate synthesis of EPO in response to hypoxia. Because the liver is the predominant source of EPO during fetal life, it has been proposed that relative insensitivity of the hepatic oxygen sensor to hypoxia explains the blunted EPO response seen in premature infants. The spontaneous resolution of the anemia that occurs by approximately 40 wk gestational age is in keeping with a developmental switch from the relatively insensitive hepatic oxygen sensor to the renal oxygen sensor, which is exquisitely sensitive to hypoxia, because by this time the predominant site of EPO synthesis has shifted to the kidneys.

The magnitude of the physiologic anemia of infancy can be modified by other ongoing processes. For example, a late hyporegenerative anemia, with absence of reticulocytes, may occur in infants with mild hemolytic disease of the newborn, requiring only phototherapy to effectively decrease the bilirubin concentration. The persistence of maternally derived anti-RBC antibodies in the infant's circulation can lead to a low-grade hemolytic anemia for several weeks, and this may present as an exaggeration of the physiologic anemia of infancy. In part, it also might reflect an impaired EPO response. Another observation is the lower than expected hemoglobin at the “physiologic” nadir seen in infants after intrauterine or neonatal RBC transfusions. When premature infants are transfused with adult blood containing Hb A, the shift of the oxygen dissociation curve as a result of the presence of Hb A facilitates delivery of oxygen to the tissues. Accordingly, the definition of anemia and the need for transfusion in premature infants must be based not only on hemoglobin level but also on oxygen requirements and the ability of an infant's circulating hemoglobin to release oxygen.

Dietary factors may also aggravate physiologic anemia. Deficiency of folic acid superimposed on the physiologic process may result in more severe anemia. Vitamin E deficiency and therapy do not appear to have a role in anemia of prematurity, despite early suggestions to the contrary. A controlled and blinded study of oral vitamin E administration (25?IU/dL-a-tocopherol, colloidal aqueous solution) to infants weighing less than 1,500?g showed no difference in hemoglobin levels, reticulocytes, RBC morphology, or platelet counts. Breast milk and modern formulas appear to provide adequate vitamin E. Oral vitamin C supplementation (50?mg/24?hr) does not cause hemolysis in premature infants. Supplemental iron starting at approximately 4?mg/kg/24?hr for preterm babies 4–8 wk old and by 4 mo in full-term infants should not cause significant hemolysis due to oxidation.

Unless perinatal blood loss has been significant, iron deficiency should not be considered as a cause of anemia in term infants in the first 4 mo of life. Assuming an infant is born with adequate iron stores, dietary iron deficiency cannot be a cause of anemia until these iron stores have been exhausted. In the absence of blood loss, this does not occur until the birthweight has approximately doubled.

Treatment.

Physiologic anemia requires no therapy other than ensuring that the diet of the infant contains essential nutrients for normal hematopoiesis, especially folic acid and iron. Premature infants who are feeding well and growing normally rarely need transfusion unless iatrogenic blood loss has been significant. In otherwise healthy premature infants, hemoglobin levels as low as 6.5?g/dL are usually well tolerated. However, the optimal level of hematocrit for premature infants is not settled (see Chapter 462). Assessment of the overall clinical condition, including growth rate, and monitoring of hematocrit are the best guides to transfusion of RBCs. RBC transfusions do not appear to affect the course of apneic spells and bradycardia. When transfusions are necessary, a volume of RBCs of 10–15?mL/kg is recommended. The number of

donors for an infant should be minimized. In early preterm infants (<1,250?g), the half-life of transfused RBCs is about 30 days.

Anemia in very-low-birthweight preterm infants may be related to a relative deficiency of EPO, and clinical trials indicate that premature infants who do not have severe illnesses and are treated with recombinant human EPO (rHuEPO) and iron

during the first 6 wk of life require fewer transfusions. The optimal timing for initiation of rHuEPO therapy and the optimal dose have yet to be determined. To achieve the best results, supplemental oral iron at a dose of at least 4–6?mg/kg/day needs to be administered. It may be possible to use parenteral iron supplements, particularly in young very-low-birthweight infants who are not able to take oral iron to reduce the need for transfusions. The cost of rHuEPO treatment currently is higher than that of RBC transfusion; however, EPO treatment may have a significant role to play in the management of infants whose parents refuse to allow blood transfusions on religious grounds.

Chapter 446 - Megaloblastic Anemias

Megaloblastic anemias have in common certain abnormalities of red blood cell (RBC) morphology and maturation. The RBCs at every stage of development are larger than normal and have an open, finely dispersed nuclear chromatin and an asynchrony between the maturation of nucleus and cytoplasm, with the delay in nuclear progression being more evident with further cell divisions. Giant metamyelocytes and bands are also present in the marrow. All megaloblastic anemias are characterized by ineffective erythropoiesis, a kinetic term that describes active erythropoiesis with premature death of cells, a decreased output of RBC from the marrow, and, consequently, anemia. In the peripheral blood, RBCs are large (increased mean corpuscular volume [MCV]) and frequently oval. Another characteristic is the presence of hypersegmented neutrophils (many neutrophils with more than four to five lobes). Almost all cases of childhood megaloblastic anemia result from a deficiency of folic acid or vitamin B_{12} ; rarely, they are caused by inborn errors of metabolism. Both vitamin B_{12} and folate are cofactors required in the synthesis of nucleoproteins, and deficiencies result in defective synthesis of DNA and, to a lesser extent, RNA and protein. Megaloblastic anemias resulting from malnutrition are relatively uncommon in the United States but important worldwide (see Chapters 4 and 42).

446.1 Folic Acid Deficiency

Folates are abundant in many foods, including green vegetables, fruits, and animal organs (liver, kidney). Folates are heat labile and water soluble, and consequently boiling or heating folate sources will lead to decreased amounts of vitamin. Naturally occurring folates are in a polyglutamated form and are absorbed less efficiently than the monoglutamate species (folic acid). Folate conjugase activity in the intestinal brush border aids the conversion of polyglutamates to the monoglutamate and thereby enhances absorption. Folic acid is absorbed throughout the small intestine, and there is an active enterohepatic circulation. Much of the folate in plasma is loosely bound to albumin. Folic acid is not biologically active. It is reduced by dihydrofolate reductase to tetrahydrofolate, which is transported into tissue cells and polyglutamated. Body stores of folate are limited, and megaloblastic anemia occurs after 2–3 mo on a folate-free diet.

Clinical Manifestations.

Mild megaloblastic anemia has been reported in very-low-birthweight infants, and routine folic acid supplementation is advised. Megaloblastic anemia has its peak incidence at 4–7 mo of age, somewhat earlier than iron deficiency anemia, although

the two may be present concomitantly in infants with poor nutrition. Besides having the usual clinical features of anemia, affected infants with folate deficiency are irritable, fail to gain weight adequately, and have chronic diarrhea. Hemorrhages from thrombocytopenia occur in advanced cases. In older children with folate deficiency the signs and symptoms are related to anemia and to any underlying pathologic process responsible for the vitamin deficiency. Folic acid deficiency may accompany kwashiorkor, marasmus, or sprue.

Etiology.

Folic acid deficiency can occur as a consequence of inadequate folate intake, decreased folate absorption, or acquired and congenital disorders of folate metabolism.

INADEQUATE FOLATE INTAKE.

Anemia due to decreased folate intake usually becomes manifest under clinical conditions where there are increased vitamin requirements (pregnancy, growth in infancy, chronic hemolysis). The normal infant daily requirement is 25–35?µg/day. The requirements on a weight basis are higher in children than adults, owing to the increased needs of growth. Human breast milk, pasteurized cow's milk. and infant formulas provide adequate amounts of folic acid. Goat's milk is deficient; folic acid supplementation must be given when it is the main food. Unless supplemented, powdered milk may also be a poor source of folic acid.

Folate requirements increase markedly during pregnancy, in part to meet fetal needs. Decreases in serum and RBC folate levels occur in as many as 25% of pregnant women at term and may be aggravated by infection. Folate supplementation of at least 400?µg/day is recommended from the start of pregnancy to prevent neural tube defects and to meet growth needs. Mothers with folate deficiency may have infants with normal folate stores, owing to selective transfer of folate to the fetus via placental folate receptors.

DECREASED FOLATE ABSORPTION.

Malabsorption due to chronic diarrheal states or diffuse inflammatory disease can lead to folate deficiency. Megaloblastic anemia due to folic acid deficiency occurs in celiac disease, chronic infectious enteritis, and in association with enteroenteric fistulas. With both inflammatory bowel disease and diarrhea some of the decreased folate absorption may be caused by impaired folate conjugase. Chronic diarrhea also interferes with the enterohepatic circulation of folate, thereby enhancing folate losses because of rapid intestinal passage. Previous intestinal surgery also can be a cause of decreased folate absorption.

Certain anticonvulsant drugs (e.g., phenytoin, primidone, phenobarbital) can impair absorption of folic acid, and many treated patients have low serum levels of folic acid. Frank megaloblastic anemia is rare, however, and responds to folic acid therapy even if administration of the offending drug is continued.

CONGENITAL ABNORMALITIES IN FOLATE METABOLISM.

Megaloblastic anemia resulting from congenital dihydrofolate reductase deficiency has been reported in several patients who were unable to form biologically active tetrahydrofolate and who developed severe megaloblastic anemia in early infancy. These patients were successfully treated with large doses of folic acid or folinic acid. Deficiency of methylene tetrahydrofolate reductase has been described in some patients with homocystinuria without hematologic abnormalities.

DRUG-INDUCED ABNORMALITIES IN FOLATE METABOLISM.

A number of drugs have anti–folic acid activity as their primary pharmacologic effect and regularly produce megaloblastic anemia. Methotrexate binds to dihydrofolate reductase and prevents formation of tetrahydrofolate, the active form. Pyrimethamine, used in the therapy of toxoplasmosis, and trimethoprim, used for treatment of various infections, may induce folic acid deficiency and, occasionally, megaloblastic anemia. Therapy with folinic acid (5-formyltetrahydrofolate) is usually beneficial.

Laboratory Findings.

The anemia is macrocytic (mean corpuscular volume > 100?fL). Variations in RBC shape and size are common (see Fig. 439–1*B*). The reticulocyte count is low, and nucleated RBCs demonstrating megaloblastic morphology are often seen in the blood. Neutropenia and thrombocytopenia

---

may be present, particularly in patients with long-standing deficiencies. The neutrophils are large, some with hypersegmented nuclei. Normal serum folic acid levels are 5–20?ng/mL; with deficiency, levels are less than 3?ng/mL. Levels of RBC folate are a better indicator of chronic deficiency. The normal RBC folate level is 150–600?ng/mL of packed cells. Levels of iron and vitamin B_{12} in serum are usually normal or elevated. Serum activity of lactate dehydrogenase (LDH) is markedly elevated. The bone marrow is hypercellular because of erythroid hyperplasia. Megaloblastic changes are prominent, although some normal RBC precursors may also be found. Large, abnormal neutrophilic forms (giant metamyelocytes) with cytoplasmic vacuolation are seen, as well as hypersegmentation of the nuclei of megakaryocytes.

Treatment.

When the diagnosis of folate deficiency is established, folic acid may be administered orally or parenterally in a dose of 0.5–1?mg/day. If the specific diagnosis is in doubt, smaller doses of folate (0.1?mg/day) may be used for a week as a diagnostic test, because a hematologic response can be expected within 72?hr. Larger doses of folate (greater than 0.1?mg) can correct the anemia of vitamin B_{12}

deficiency but may aggravate any associated neurologic abnormalities. In most medical settings in developed countries, this therapeutic trial to distinguish the different causes of megaloblastic anemia rarely is necessary because vitamin B_{12} and folate blood levels usually are readily available. Transfusions are indicated only when the anemia is severe or the child is very ill. Folic acid therapy (0.5–1.0?mg/day) should be continued for 3–4 wk until a definite hematologic response has occurred. Maintenance therapy with a multivitamin (containing 0.2?mg folate) is adequate.

446.2 Vitamin B_{12} (Cobalamin) Deficiency

Vitamin B_{12} is derived from cobalamin in food (mainly animal sources) secondary to production by microorganisms. Humans cannot synthesize vitamin B_{12} . The cobalamins are released in the acidity of the stomach and combine there with R proteins and intrinsic factor (IF), traverse the duodenum, where pancreatic proteases break down the R proteins, and are absorbed in the distal ileum via specific receptors for IF-cobalamin. In addition, some vitamin B_{12} from large doses may diffuse through mucosa in the intestine and mouth. In the plasma, cobalamin binds to a transport protein, transcobalamin II (TC-II), which carries the vitamin B_{12} to the liver, bone marrow, and other tissue storage sites. TC-II enters cells by receptor-mediated endocytosis, and cobalamin is converted to active forms (methylcobalamin and adenosylcobalamin) important in the transfer of methyl groups and DNA synthesis. Plasma also contains two other vitamin B_{12} –binding proteins, transcobalamin I and III (TC-I and TC-III). These latter two forms of transcobalamin have no specific transport role but are known to reflect vitamin B_{12} tissue stores. In fact, almost all vitamin B_{12} in plasma is bound to TC-I and TC-III and thus the measurement of serum B_{12} concentration reflects the storage of this vitamin. In contrast to folate stores, older children and adults have sufficient vitamin B_{12} stores to last 3–5 yr. However, in young infants born to mothers with low vitamin B_{12} stores, clinical signs of cobalamin deficiency can become apparent in the first 4–5 mo of life.

Etiology.

Vitamin B_{12} deficiency may result from inadequate dietary intake of vitamin, lack of IF secretion by the stomach, impaired intestinal absorption of IF-cobalamin, or absence of vitamin B_{12} transport protein.

INADEQUATE VITAMIN B_{12} INTAKE.

Because vitamin B_{12} is present in many foods, dietary deficiency is rare. It may occur in cases of extreme dietary restriction (strict vegetarians or vegans) in which no animal products are consumed. Vitamin B_{12} deficiency is not common in kwashiorkor or infantile marasmus. In children, megaloblastic anemia from inadequate intake of vitamin B_{12} occurs in breast-fed infants whose mothers are vegans or themselves have pernicious anemia. Maternal pernicious anemia may be manifest by reduced serum vitamin B_{12} with or without macrocytic anemia in the mother. This cause of childhood megaloblastic anemia often appears in the first year of life.

LACK OF INTRINSIC FACTOR.

Congenital pernicious anemia is a rare autosomal recessive disorder due to an inability to secrete gastric IF or secretion of functionally abnormal IF. It differs from the typical disease in adults in that the stomach secretes acid normally and is histologically normal. There are no antibodies to parietal cells and no associated endocrine disorders. The symptoms of juvenile pernicious anemia become prominent at around 1 yr of age. This interval is consistent with exhaustion of the stores of vitamin B_{12} acquired in utero. As the anemia becomes severe, weakness, irritability, anorexia, and listlessness occur. The tongue is smooth, red, and painful. Neurologic manifestations include ataxia, paresthesias, hyporeflexia, Babinski responses, and clonus. *Juvenile pernicious anemia* is another rare disorder occurring in older children. It is an immunologic disorder akin to adult-type pernicious anemia. There may be atrophy of the gastric mucosa, achlorhydria, and antibodies in serum against IF and parietal cells. These children may have additional immunologic abnormalities, cutaneous candidiasis, hypoparathyroidism, and other endocrine deficiencies. An abnormal Schilling result is corrected by addition of exogenous IF. Parenteral vitamin B_{12} should be administered regularly to these patients. *Gastric surgery* can lead to intrinsic factor deficiency, and susceptible individuals need lifelong parenteral vitamin B_{12} supplementation.

IMPAIRED VITAMIN B_{12} ABSORPTION.

Patients with inflammatory diseases such as regional enteritis or neonatal necrotizing enterocolitis may have impaired absorption of vitamin B_{12} . When the terminal ileum has been surgically removed, lifelong parenteral administration should be used if there is evidence that vitamin B_{12} is not absorbed. An overgrowth of intestinal bacteria within diverticula or duplications of the small intestine may cause vitamin B_{12} deficiency by consumption of or competition for the vitamin or by splitting of its complex with IF. In these cases, hematologic response may follow appropriate antibiotic therapy. Similar mechanisms may operate when the fish tapeworm *Diphyllobothrium latum* infests the upper small intestine. When megaloblastic anemia occurs in these situations, the serum vitamin B_{12} level is low, the gastric juice contains intrinsic factor, and the abnormal Schilling test result is not corrected by addition of exogenous IF.

Rare cases have been reported of familial occurrence of absence or defect of the receptor for IF-B_{12} in the terminal ileum, in some instances associated with proteinuria (*Imerslund-Grasbeck syndrome*). Decreased receptor activity may be detected in the urine of affected patients by a radioisotope binding assay. Histology of the stomach is normal, and IF and acid are present in gastric secretions. This autosomal recessive disorder is caused by defects in the *CUBN* gene on chromosome 10p12.1, resulting in decreased expression of the IF-B_{12} receptor cubilin. Parenteral treatment with vitamin B_{12} monthly corrects the deficiency.

ABSENCE OF VITAMIN B_{12} TRANSPORT PROTEIN.

Transcobalamin II (TC-II) deficiency is a rare cause of megaloblastic anemia due to decreased utilization of cobalamin. TC-II is the principal physiologic transport vehicle for vitamin B_{12} . The role of TC-II in B_{12} transport is similar to that of transferrin (Tf) for iron; specific receptors for TC-II and Tf exist on cells needing vitamin B_{12} or iron. A congenital deficiency is inherited

---

as an autosomal recessive condition, with failure to absorb and transport vitamin B_{12} . Most patients lack TC-II, but some have functionally defective forms. Serum vitamin B_{12} levels are normal because the storage forms of cobalamin, TC-I and TC-III, are not affected. This disorder usually manifests in the first weeks of life. Characteristically, there is failure to thrive, diarrhea, vomiting, glossitis, neurologic abnormalities, and megaloblastic anemia. The diagnosis of this disorder is suggested by the presence of severe megaloblastic anemia with normal serum vitamin B_{12} and folate levels and no evidence of any other inborn errors of metabolism. The diagnosis is made by specific tests for TC-II. The serum vitamin B_{12} levels must be kept high to utilize cobalamin. Hence, the therapy for this disorder is large parenteral doses of vitamin B_{12} given twice a week for life. These frequent and large doses of cobalamin appear to overcome the transport deficiency. Most children with this disorder die if treatment is not provided in infancy.

Clinical Manifestations.

Children with cobalamin deficiency often present with nonspecific manifestations such as weakness, fatigue, failure to thrive, or irritability. Other common findings include pallor, glossitis, vomiting, diarrhea, and icterus. Neurologic symptoms also occur, and these include paresthesias, sensory deficits, hypotonia, seizures, developmental delay, developmental regression, and neuropsychiatric changes. Neurologic problems from vitamin B_{12} deficiency can occur in the absence of any hematologic abnormalities.

Laboratory Findings.

The hematologic manifestations of folate and cobalamin deficiency are identical. The anemia resulting from cobalamin deficiency is macrocytic, with prominent macro-ovalocytosis of the RBCs (see Fig. 439–1*B*). The neutrophils may be large and hypersegmented. In advanced cases, neutropenia and thrombocytopenia, simulating aplastic anemia or leukemia, occur. Serum vitamin B_{12} levels are less than 100?pg/mL. Concentrations of serum iron and serum folic acid are normal or elevated. Serum LDH activity is markedly increased, a reflection of the ineffective erythropoiesis. Moderate elevations (2–3?mg/dL) of serum bilirubin levels also may be found. Excessive excretion of methylmalonic acid in the urine (normal amount, 0–3.5?mg/24?hr) is a reliable and sensitive index of vitamin B_{12} deficiency.

Diagnosis.

The specific cause of vitamin B_{12} often is apparent from the clinical history. In cases where there is a reasonable explanation for decreased vitamin B_{12} absorption (previous gastric or ileal surgery) it may be reasonable to start appropriate therapy without further evaluation. In very young children in whom dietary insufficiency may be a factor, evaluation of the mother for anemia and serum vitamin B_{12} often is rewarding. If there is no obvious cause for decreased serum vitamin B_{12} , absorption of vitamin B_{12} is usually assessed by the **Schilling test**. When a normal person ingests a small amount of vitamin B_{12} into which ^{57} Co has been incorporated, the radioactive vitamin combines with the IF in stomach secretions and passes to the terminal ileum, where absorption occurs. Because the absorbed vitamin is bound to TC-II and incorporated into tissues, little or none is normally excreted in the urine. If a large dose (1?mg) of nonradioactive vitamin B_{12} is injected parenterally after 2?hr ("flushing dose"), 10–30% of the previously absorbed radioactive vitamin appears in the urine in 24?hr. Children with pernicious anemia usually excrete 2% or less under these conditions. To confirm that absence of IF is the basis of the vitamin B_{12} malabsorption, 30?mg of IF is given with a second dose of radioactive vitamin B_{12} . Normal amounts of radioactive vitamin should now be absorbed and flushed out in the urine. On the other hand, when vitamin B_{12} malabsorption results from absence of ileal receptor sites or other intestinal causes, no improvement in absorption occurs with IF. The Schilling test result remains abnormal in patients with pernicious anemia, even when therapy has completely reversed the hematologic and neurologic manifestations of the disease.

Treatment.

A prompt hematologic response follows parenteral administration of vitamin B_{12} (1?mg), usually with reticulocytosis in 2–4 days, unless there is concurrent inflammatory disease. The physiologic requirement for vitamin B_{12} is 1–5?µg/day, and hematologic responses have been observed with these small doses, indicating that administration of a minidose may be used as a therapeutic test when the diagnosis of vitamin B_{12} deficiency is in doubt. If there is evidence of neurologic involvement, 1?mg should be injected intramuscularly daily for at least 2 wk. Maintenance therapy is necessary throughout a patient's life; monthly intramuscular administration of 1?mg of vitamin B_{12} is sufficient. Oral therapy may succeed because of mucosal diffusion with high doses, but it is not generally advisable, owing to uncertainty of absorption.

446.3 Other Rare Megaloblastic Anemias

Oroticaciduria is a rare autosomal recessive disorder that usually appears in the first year of life and is characterized by growth failure, developmental retardation, megaloblastic anemia, and increased urinary excretion of orotic acid (see Chapter 78). This defect, the most common metabolic error in the de novo synthesis of pyrimidines, therefore affects nucleic acid synthesis. The usual form of hereditary orotic aciduria is caused by a deficiency (in all body tissues) of both orotic

phosphoribosyl transferase (OPT) and orotidine-5-phosphate decarboxylase (ODC), two sequential enzymatic steps in pyrimidine nucleotide synthesis. The diagnosis of this disorder is suggested by the presence of severe megaloblastic anemia with normal serum B_{12} and folate levels and no evidence of TC-II deficiency. A presumptive diagnosis is made by finding increased urinary orotic acid. Confirmation of the diagnosis, however, requires assay of the transferase and decarboxylase enzymes in the patient's erythrocytes. Physical and mental retardation are frequently present. The anemia is refractory to vitamin B_{12} or folic acid but responds promptly to administration of the pyrimidine uridine (100–150?µg/kg/24?hr). Megaloblastic anemia can also occur in the *Lesch-Nyhan syndrome*, in which regeneration of purine nucleotides is blocked (see Chapter 78).

Thiamine-responsive megaloblastic anemia (TRMA) is a syndrome characterized by megaloblastic anemia, sensorineural deafness, diabetes mellitus, and, occasionally, cardiomyopathy and optic nerve atrophy. It previously had been observed that the megaloblastic anemia in some patients responded to high doses of thiamine. It now is known that the defect in this disorder is due to an abnormality in a thiamine transport gene located on chromosome 1. This is an autosomal recessive disorder presenting in childhood and occurring in several ethnically distinct populations.

Deficiency of adenosylcobalamin and methylcobalamin along with megaloblastic anemia has been encountered in a few children with inability to convert cobalamin to its biologically active metabolites. These disorders are characterized by neurologic abnormalities and either methylmalonic aciduria, homocystinuria, or both. Abnormalities are usually noted in the early weeks of life and include failure to thrive, lethargy, hypotonia, macrocytosis with megaloblastic bone marrow changes and anemia or pancytopenia, and hepatic dysfunction. The megaloblastic changes may reverse and other symptoms may improve with hydroxycobalamin treatment, 1?mg/24?hr IM initially, gradually changed to a dose two to three times per week, then once a month.

Chapter 447 - Iron-Deficiency Anemia

Anemia resulting from lack of sufficient iron for synthesis of hemoglobin is the most common hematologic disease of infancy and childhood. Its frequency is related to certain basic aspects of iron metabolism and nutrition. The body of a newborn infant contains about 0.5?g of iron, whereas the adult content is estimated at 5?g. To make up for this discrepancy, an average of 0.8?mg of iron must be absorbed each day during the first 15 yr of life. In addition to this growth requirement, a small amount is necessary to balance normal losses of iron by shedding of cells. Accordingly, to maintain positive iron balance in childhood, about 1?mg of iron must be absorbed each day.

Iron is absorbed in the proximal small intestine, mediated in part by a variety of duodenal proteins. Because absorption of dietary iron is assumed to be about 10%, a diet containing 8–10?mg of iron daily is necessary for optimal nutrition. Iron is absorbed two to three times more efficiently from human milk than from cow's milk, perhaps partly because of differences in calcium content. Breast-fed infants may, therefore, require less iron from other foods. During the first years of life, because relatively small quantities of iron-rich foods are eaten, it is often difficult to attain sufficient iron. For this reason, the diet should include such foods as infant cereals or formulas that have been fortified with iron; both of these are very effective in preventing iron deficiency. Formulas with 7–12?mg Fe/L for full-term infants and premature infant formulas with 15?mg/L for infants less than 1,800?g at birth are effective. Infants breast-fed exclusively should receive iron supplementation from 4 mo of age. At best, an infant is in a precarious situation with respect to iron. Should the diet become inadequate or external blood loss occur, anemia ensues rapidly.

Adolescents are also susceptible to iron deficiency because of high requirements due to the growth spurt, dietary deficiencies, and menstrual blood loss. In the United States, about 9% of 1–2 yr-old children are iron deficient; 3% have anemia. Of adolescent girls, 9% are iron deficient and 2% have anemia. In boys, a 50% decrease in stored iron occurs as puberty progresses.

Etiology.

Low birthweight and unusual perinatal hemorrhage are associated with decreases in neonatal hemoglobin mass and stores of iron. As the high hemoglobin concentration of the newborn infant falls during the first 2–3 mo of life, considerable iron is reclaimed and stored. These reclaimed stores are usually sufficient for blood

formation in the first 6–9 mo of life in term infants. In low-birthweight infants or those with perinatal blood loss, stored iron may be depleted earlier and dietary sources become of paramount importance. In term infants, anemia caused solely by inadequate dietary iron is unusual before 6 mo and usually occurs at 9–24 mo of age. Thereafter, it is relatively infrequent. The usual dietary pattern observed in infants with iron-deficiency anemia is consumption of large amounts of cow's milk and of foods not supplemented with iron.

Blood loss must be considered a possible cause in every case of iron-deficiency anemia, particularly in older children. Chronic iron-deficiency anemia from occult bleeding may be caused by a lesion of the gastrointestinal tract, such as a peptic ulcer, Meckel diverticulum, polyp, or hemangioma, or by inflammatory bowel disease. In some geographic areas, hookworm infestation is an important cause of iron deficiency. Pulmonary hemosiderosis may be associated with unrecognized bleeding in the lungs and recurrent iron deficiency after treatment with iron. Chronic diarrhea in early childhood may be associated with considerable unrecognized blood loss. Some infants with severe iron deficiency in the United States have chronic intestinal blood loss induced by exposure to a heat-labile protein in whole cow's milk. Loss of blood in the stools each day can be prevented either by reducing the quantity of whole cow's milk to 1 pint/24?hr or less, by using heated or evaporated milk, or by feeding a milk substitute. This gastrointestinal reaction is not related to enzymatic abnormalities in the mucosa, such as lactase deficiency, or to typical “milk allergy.” Involved infants characteristically develop anemia that is more severe and occurs earlier than would be expected simply from an inadequate intake of iron.

Histologic abnormalities of the mucosa of the gastrointestinal tract, such as blunting of the villi, are present in advanced iron-deficiency anemia and may cause leakage of blood and decreased absorption of iron, further compounding the problem.

Intense exercise conditioning, as occurs in competitive athletics in high school, may result in iron depletion in girls; this occurs less commonly in boys.

Clinical Manifestations.

Pallor is the most important sign of iron deficiency. In mild to moderate iron deficiency (hemoglobin levels of 6–10?g/dL), compensatory mechanisms, including increased levels of 2,3-diphosphoglycerate (2,3-DPG) and a shift of the oxygen dissociation curve, may be so effective that few symptoms of anemia are noted, although affected children may be irritable. Pagophagia, the desire to ingest unusual substances such as ice or dirt, may be present. In some children, ingestion of lead-containing substances may lead to concomitant plumbism. When the hemoglobin level falls below 5?g/dL, irritability and anorexia are prominent. Tachycardia and cardiac dilation occur, and systolic murmurs are often present.

Children with iron deficiency anemia may be obese or may be underweight, with other evidence of poor nutrition. The irritability and anorexia characteristic of advanced cases may reflect deficiency in tissue iron, because with iron therapy striking improvement in behavior frequently occurs before significant hematologic improvement is noted.

Iron deficiency may have effects on neurologic and intellectual function. A number of reports suggest that iron-deficiency anemia, and even iron deficiency without significant anemia, affects attention span, alertness, and learning of both infants and adolescents. In a controlled trial, adolescent girls with serum ferritin levels of 12?ng/L or less but without anemia had improved verbal learning and memory after taking iron for 8 wk.

Some of the clinical manifestations may be related to the role of iron in certain enzymatic reactions. Monoamine oxidase (MAO), an iron-dependent enzyme, has a crucial role in neurochemical reactions in the central nervous system. Iron deficiency produces decreases in the activities of enzymes such as catalase and cytochromes. Catalase and peroxidase contain iron, but their biologic essentiality is not well established. Administration of iron may decrease the frequency of breath-holding spells, suggesting a role for iron deficiency or anemia.

Laboratory Findings.

In progressive iron deficiency, a sequence of biochemical and hematologic events occurs. First, the tissue iron stores represented by bone marrow hemosiderin disappear. The level of serum ferritin, an iron-storage protein, provides a relatively accurate estimate of body iron stores in the absence of inflammatory disease. Normal ranges are age dependent, and decreased levels accompany iron deficiency. Next, serum iron level decreases (also age dependent), the iron-binding capacity of the serum (serum transferrin) increases, and the percent saturation (transferrin saturation) falls below normal. When the availability of iron becomes rate limiting for hemoglobin synthesis, free erythrocyte protoporphyrins (FEP) accumulates.

As the deficiency progresses, the red blood cells (RBCs) become smaller than normal and their hemoglobin content decreases. The morphologic characteristics of RBCs are best quantified by the determination of mean corpuscular hemoglobin

(MCH) and mean corpuscular volume (MCV). Developmental changes in MCV require the use of age-related standards for diagnosis of microcytosis (see Table 439–1). With increasing deficiency, the RBCs become deformed and misshapen and present characteristic microcytosis, hypochromia, poikilocytosis, and increased RBC distribution width (RDW) (see Fig. 439–1*C*). The reticulocyte percentage may be normal or moderately elevated, but absolute reticulocyte counts indicate an insufficient response to anemia. Nucleated RBCs occasionally are seen in the peripheral blood if the anemia is severe. White blood cell counts are normal. Sometimes there is a striking thrombocytosis (600,000–1 million/mm^3). Just as in the case of transient erythroblastopenia of childhood, thrombocytosis presumably is caused by increased erythropoietin, which is known to have some structural homology with thrombopoietin. However, it should also be noted that very severe iron-deficiency anemia occasionally may be associated with thrombocytopenia, and this can confuse the diagnosis with other bone marrow failure disorders. The bone marrow is hypercellular, with erythroid hyperplasia. The normoblasts may have scanty, fragmented cytoplasm with poor hemoglobination. Leukocytes and megakaryocytes are normal. There is no stainable iron in marrow reticulum cells. In about a third of cases, occult blood can be detected in the stools.

Differential Diagnosis.

Iron deficiency must be differentiated from other hypochromic microcytic anemias. The most common scenario is the need to distinguish iron deficiency from a– and ß–thalassemia trait and other hemoglobinopathies, particularly those related to hemoglobin E (see Chapter 454). A simple distinguishing feature of the latter conditions is that the RBC count often is elevated above normal despite the presence of a mild anemia and microcytosis; and this is in marked contrast to iron deficiency in which the RBC count decreases along with the reduced hemoglobin and MCV. Another difference between a– and ß–thalassemia trait and iron deficiency is that the RDW is elevated in iron deficiency.

ß-Thalassemia trait occurs in people from the Mediterranean area, Africa, and Asia. It is a mild microcytic anemia characterized by elevated levels of hemoglobin A_2 and/or increased fetal hemoglobin concentration; serum iron, total iron-binding capacity (transferrin), and ferritin are normal; and no abnormal hemoglobin is seen on electrophoresis. *Homozygous ß-thalassemia* (or *thalassemia major*), with its pronounced erythroblastosis and severe hemolytic component, should present no diagnostic confusion.

a-Thalassemia trait occurs in blacks, Chinese, and Southeast Asians. This mild microcytic disorder is caused by a deletion of two of four genes that regulate a-globin production. In the usual clinical setting the diagnosis of a-thalassemia trait can be assumed when a patient with a familial hypochromic microcytic anemia has normal results of iron studies (including ferritin), normal levels of Hb A2 and Hb F, and a normal hemoglobin electrophoresis. It is a diagnosis of exclusion except in the newborn period when infants with a-thalassemia trait have 3–10% hemoglobin Barts ($?_4$) (see Chapter 454). A specific diagnosis for a-thalassemia disorders is possible using molecular diagnostic strategies, which are also important for prenatal diagnosis.

Hb H disease, another form of a-thalassemia results from deletion of three of the four a-globin genes. It also is characterized by hypochromia and microcytosis, but in addition there is a mild hemolytic component from instability of the ß-chain tetramers (Hb H) resulting from a deficiency of a-globin chains. Beyond infancy, Hb H is readily identified by hemoglobin electrophoresis. During the newborn period, the moderately severe a-globin deficiency allows for the accumulation of more ? chains and the concentration of hemoglobin Barts is over 20%.

The *anemia of chronic disease (ACD)* and infection is usually normocytic, although occasionally it may be slightly microcytic. In contrast to iron-deficiency anemia, in these inflammatory conditions both the serum iron level and iron-binding capacity (transferrin) are reduced and serum ferritin levels are normal or elevated. The serum transferrin receptor (TfR) level is useful in the distinction between iron-deficiency anemia and anemia of chronic disease because it is not affected by inflammation. The concentration of TfR is elevated in iron deficiency and is within the normal range in anemia of chronic disease. An elevation of the TfR/log ferritin ratio is especially sensitive in detecting iron-deficiency anemia.

Lead poisoning and iron-deficiency anemia both are associated with elevations of FEP. In cases of lead poisoning associated with iron deficiency, the RBCs are morphologically similar but coarse basophilic stippling of the RBCs is frequently prominent. Elevations of blood lead, FEP, and urinary coproporphyrin levels are seen (see Chapter 703).

Treatment.

The regular response of iron-deficiency anemia to adequate amounts of iron is an important diagnostic and therapeutic feature. Oral administration of simple ferrous salts (sulfate, gluconate, fumarate) provides inexpensive and satisfactory therapy. No evidence shows that addition of any trace metal, vitamin, or other hematinic substance significantly increases the response to simple ferrous salts. The therapeutic dose should be calculated in terms of elemental iron; ferrous sulfate is 20% elemental iron by weight. A daily total of 4–6?mg/kg of elemental iron in three divided doses provides an optimal amount of iron for the stimulated bone marrow to use. Intolerance to oral iron is uncommon in young children, although older children and adolescents sometimes have gastrointestinal complaints. A parenteral iron preparation (iron dextran) is an effective form of iron and is usually safe when given in a properly calculated dose, but the response to parenteral iron is no more rapid or complete than that obtained with proper oral administration of iron, unless malabsorption is a factor.

While adequate iron medication is given, the family must be educated about the patient's diet, and the consumption of milk should be limited to a reasonable quantity, preferably 500?mL (1 pint)/24?hr or less. This reduction has a dual effect: The amount of iron-rich foods is increased, and blood loss from intolerance to cow's milk proteins is reduced. When the re-education of child and parent is not successful, parenteral iron medication may be indicated. Iron deficiency can be prevented in high-risk populations by providing iron-fortified formula or cereals during infancy.

Within 72–96?hr after administration of iron to an anemic child, peripheral reticulocytosis is noted (Table 447–1). The height of this response is inversely proportional to the severity of the anemia. Reticulocytosis is followed by a rise in the hemoglobin level, which may increase as much as 0.5?g/dL/24?hr. Iron medication should be continued for 8 wk after blood values are normal. Failures of iron therapy occur when a child does not receive the prescribed medication, when iron is given in a form that is poorly absorbed, or when there is continuing unrecognized blood loss, such as intestinal or pulmonary loss, or loss with menstrual periods. An incorrect original diagnosis of nutritional iron deficiency may be revealed by therapeutic failure of iron medication.

Because a rapid hematologic response can be confidently predicted in typical iron deficiency, blood transfusion is indicated only when the anemia is very severe or when superimposed infection may interfere with the response. It is not necessary to attempt rapid correction of severe anemia by transfusion; the procedure may be dangerous because of associated hypervolemia and cardiac dilatation. Packed or sedimented RBCs should be administered slowly in an amount sufficient to raise the hemoglobin to a safe level at which the response to iron therapy can be awaited. In general, severely anemic children with hemoglobin values less than 4?g/dL should be given only

TABLE 447-1 -- Responses to Iron Therapy in Iron-Deficiency Anemia

Time After Iron Administration	Response
12–24 hr	Replacement of intracellular iron enzymes; subjective improvement; decreased irritability; increased Appetite
36–48 hr	Initial bone marrow response; erythroid hyperplasia
48–72 hr	Reticulocytosis, peaking at 5–7 days
4–30 days	Increase in hemoglobin level
1–3 mo	Repletion of stores

2–3?mL/kg of packed cells at any one time (furosemide may also be administered as a diuretic). If there is evidence of frank congestive heart failure, a modified exchange transfusion using fresh-packed RBCs should be considered, although diuretics followed by slow infusion of packed RBCs may suffice.

Chapter 448 - Other Microcytic Anemias

Sideroblastic Anemias.

Sideroblastic anemias result from acquired and hereditary disorders of heme synthesis. The anemias are characterized by hypochromic microcytic red blood cells (RBCs) mixed with normal RBCs, thus giving an overall picture of a dimorphic population of erythrocytes, and the complete blood cell count indicates an extremely high RBC distribution width (RDW). The serum iron concentration usually is elevated, and the transferrin saturation of iron is increased. In all cases of sideroblastic anemia, regardless of the specific cause, impaired heme synthesis leads to retention of iron within the mitochondria. Morphologically, this is seen in marrow nucleated RBCs with iron granules (i.e., aggregates of iron in mitochondria) that have a perinuclear distribution. These unusual cells, known as ringed sideroblasts, are found only in pathologic states and are distinct from the sideroblasts in the marrows of normal subjects (i.e., RBC precursors that contain diffused cytoplasmic ferritin granules). Sideroblastic anemias most commonly occur in adulthood, and these acquired disorders can be idiopathic or secondary to drugs, alcohol, or myelodysplastic disorders. A few sideroblastic anemias are seen in children.

CONGENITAL SIDEROBLASTIC ANEMIA.

This rare sideroblastic anemia usually conforms to an X-linked pattern of inheritance, and it usually occurs in males, although skewed lyonization has resulted in affected females. Autosomal dominant and sporadic cases also occur. Hereditary sideroblastic anemias result from abnormalities of the erythrocytic isozyme for 5-aminolevulinic acid synthetase (ALAS), the rate-limiting enzyme reaction in heme synthesis. An important cofactor for ALAS is pyridoxal phosphate. The gene for the erythrocyte-specific ALAS (*ALAS2*) is located on the X chromosome, and over 20 different missense mutations have been identified. Several of these mutations occur near the binding site for pyridoxal phosphate.

Severe anemias are recognized in infancy or early childhood whereas milder cases may not become apparent until early adulthood or later. Clinical findings include pallor, icterus, and moderate splenomegaly and/or hepatomegaly. The severity of the anemia varies such that some patients require no therapy while others need regular RBC transfusions. A subset of patients with hereditary sideroblastic anemia manifest a hematologic response to pharmacologic doses of pyridoxine. Iron overload as manifested by elevated serum ferritin, elevated serum iron, and increased transferrin saturation is a major complication of this disorder. In some cases in which there is little or no anemia there still may be clinical evidence of iron overload (e.g., diabetes mellitus, liver dysfunction). Stem cell transplantation has been utilized for affected

children who were RBC transfusion dependent.

A unique variant of congenital sideroblastic anemia is **Pearson's syndrome**, characterized by the early onset of transfusion-dependent anemia, neutropenia, and thrombocytopenia. In addition to the usual marrow abnormalities of sideroblastic anemia, these children also have vacuolization of RBC and myeloid precursors. In contrast to other sideroblastic anemias that are microcytic, this is a macrocytic anemia and, for this reason, it often is sometimes confused with Diamond-Blackfan anemia (see Chapter 440).

Lead Poisoning.

See Chapter 703 .

Rare Types of Hypochromic Microcytic Anemia.

Isolated cases of hypochromic microcytic anemia with other abnormalities of iron metabolism are known; some patients have had defects in iron mobilization or reutilization. *Congenital absence of iron-binding protein* (atransferrinemia) is a very rare disorder associated with severe hypochromic anemia despite iron overload and requires infusions of apo-transferrin and iron chelation therapy, although the latter may be avoided if the transferrin infusions are started early. Iron is absorbed normally and is deposited in the visceral organs rather than in bone marrow.

Several patients have had refractory hypochromic anemia associated with lymphatic tumors or lymphoid hyperplasia. Correction of the anemia followed removal of the abnormal lymphatic tissue in these patients. (See also Chapters 481 and 498 .)

Section 3 - *Hemolytic Anemias*

Chapter 449 - Definitions and Classification of Hemolytic Anemias

George B. Segel

Hemolysis is defined as the premature destruction of red blood cells (RBCs). If the rate of destruction exceeds the capacity of the marrow to produce RBCs, anemia results. Normal RBC survival time is 110–120 days (half-life, 55–60 days), and approximately 1% of RBCs (the senescent ones) are removed each day and replaced by the marrow to maintain the RBC count. During hemolysis, RBC survival is shortened and increased marrow activity results in a heightened reticulocyte percentage and number. Hemolysis should be suspected as a cause of anemia if an elevated reticulocyte count is present. The reticulocyte count also may be elevated as a response to acute blood loss or for a short period after replacement therapy for iron, vitamin B_{12} , or folate deficiencies. The marrow can increase its output two- to threefold acutely, with a maximum of six- to eightfold if hemolysis is of long standing. The reticulocyte percentage can be corrected to measure the magnitude of the marrow production in response to hemolysis as follows:

where μ is a maturation factor related to the severity of the anemia (Fig. 449–1). The normal reticulocyte index is 1.0.

As anemia becomes more severe, there is more erythropoietin stimulation of erythropoiesis, and *reticulocytes* are released from the marrow earlier, spending more than 1 day as reticulocytes in the blood. In terms of measuring the marrow response, it is inappropriate to count reticulocytes produced yesterday in today's calculation of the reticulocyte index. The maturation factor, μ, provides this correction (see Fig. 449–1). The usual marrow response in a chronic hemolytic anemia is reflected by a

Figure 449-1 Number of days for maturation of reticulocytes in the marrow and blood. The duration of

maturation as blood reticulocytes is taken as µ. (Modified from Hillman RS, Finch CA: *Red Cell Manual*. Philadelphia, FA Davis, 1983.)

reticulocyte index of 3–4, with a maximum of 6–8 corresponding to maximal marrow output.

The *erythroid hyperplasia* resulting from chronic hemolytic anemia in children, especially thalassemia, may be so extensive that the medullary spaces expand at the expense of the cortical bone. These changes may be evident on physical examination or on radiographs of the skull and long bones (see Fig. 454–3). A propensity to fracture long bones can also occur.

Direct assessment of the severity of hemolysis requires measurement of the RBC survival time using RBCs tagged with the radioisotope $Na_2{}^{51}CrO_4$. The normal value for the ^{51}Cr half-life is 25–35 days. This value is less than the expected half-life of 55–60 days because of the elution of ^{51}Cr from the labeled RBCs at the rate of about 1% per day.

Several other plasma, urinary, or fecal chemical alterations reflect the presence of hemolysis. The exaggerated *degradation of hemoglobin* results in increased biliary excretion of heme pigment derivatives and increased fecal urobilinogen (Fig. 449–2). Gallstones composed of calcium bilirubinate may be formed in children with chronic hemolysis as young as 4 yr of age.

Figure 449-2 Red cell destruction and the catabolism of hemoglobin (Hb) based on the description by Hillman and Finch. (From Hillman RS, Finch CA: *Red Cell Manual*. Philadelphia, FA Davis, 1983.)

Elevations of serum unconjugated bilirubin also may accompany hemolysis.

Three heme-binding proteins in the plasma are altered during hemolysis (see Fig. 449–2). Hemoglobin binds to haptoglobin and hemopexin, both of which are cleared more rapidly as conjugates and their plasma concentration is decreased. Oxidized heme binds to albumin to form methemalbumin, which is increased. When the capacity of these binding molecules is exceeded, free hemoglobin appears in the plasma, and the pink color can be seen if the RBCs are sedimented in a capillary hematocrit tube. If present, free hemoglobin in the plasma is prima facie evidence of intravascular hemolysis. Free hemoglobin dissociates into dimers and is filtered by the kidneys. When the tubular reabsorptive capacity of the kidneys for hemoglobin is exceeded, free hemoglobin appears in the urine. Even in the absence of hemoglobinuria, iron loss may result from reabsorbed hemoglobin and the shedding of renal epithelial cells in which the iron from hemoglobin is stored as hemosiderin. This may lead to secondary iron deficiency during chronic intravascular hemolysis. When hemoglobin is degraded, an a-methene bridge is broken in the cyclic tetrapyrrole of the heme moiety, with release of carbon monoxide (CO) (see Fig. 449–2). The amount of CO in the blood or expired air provides a dynamic measure of the hemolytic rate. End-tidal CO is used as a research tool but is not used in clinical laboratories to measure hemolysis.

The hematocrit during hemolysis is dependent on the severity of the hemolysis and on the marrow response in producing RBCs. The shortened RBC life span and heightened RBC production result in a marked susceptibility to *aplastic* or *hypoplastic crises*, characterized by erythroid marrow failure and reticulocytopenia, accompanied by a rapid further reduction in hemoglobin and hematocrit to extremely low levels. The most common cause of aplastic crises is parvovirus B19, which is erythrocytotropic in marrow culture in vitro (see Chapters 230 and 454). Aplastic crises may produce a precipitous and life-threatening decline in the hematocrit, which usually lasts 10–14 days. Such transient erythroid marrow failure has only a mild effect on persons with a normal RBC life span but has a proportionately greater effect as the RBC life span is shortened by hemolysis. A second infection with parvovirus is uncommon, but other infections may compromise the erythroid marrow output, resulting in various degrees of hypoplasia or hypoplastic crises.

The hemolytic anemias may be classified as either (1) cellular, resulting from intrinsic abnormalities of the membrane, enzymes, or hemoglobin; or (2) extracellular, resulting from antibodies, mechanical factors, or plasma factors. Most of the cellular defects are inherited (paroxysmal nocturnal hemoglobinuria is acquired), and most of the extracellular defects are acquired (abetalipoproteinemia with acanthocytosis is inherited). Table 449–1 shows the most common hemolytic anemias, their underlying defects, the diagnostic laboratory tests, and the current recommendations for treatment.

TABLE 449-1 -- Hemolytic Anemias and Their Treatment

Diagnosis	Defect	Laboratory Tests	Treatment
Cellular Defects			
Membrane Defects			
Hereditary spherocytosis	Cytoskeletal protein defects	Spherocytes on blood film	If Hb > 10 g/dL and retic < 10%–none
	Frequently involve vertical interactions of spectrin ankyrin, protein 3	Negative Coombs test eliminates immune hemolysis	If severe anemia, poor growth, aplastic crises and age < 2 yr–transfusion
		Increased incubated osmotic fragility	If Hb < 10 g/dL and retic > 10% or massive spleen-splenectomy, preferably > age 6 yr but earlier if necessary
		Abnormal cytoskeletal protein analysis	
			Folic acid, 1 mg qd

Hereditary elliptocytosis	Cytoskeletal protein defects	Elliptocytes on blood film	Mild types–no treatment
	Frequently involve horizontal interactions of spectrin, protein 4.1, glycophorin C	RBCs mildly heat sensitive	Chronic hemolysis—transfusion and splenectomy as recommended for spherocytosis (above)
		Abnormal cytoskeletal protein analysis	
			Folic acid, 1 mg qd
Hereditary pyropoikilocytosis	Cytoskeletal protein defects	Extreme variation in RBC size and shape on blood film	Transfusion and splenectomy as recommended for spherocytosis (above)
	Homozygous or double heterozygous abnormality in horizontal interactions of a spectrin		
		Thermal sensitivity-fragmentation at 45℃ for 15 min	Folic acid 1 mg qd
Hereditary stomatocytosis	Cytoskeletal protein defects	Stomatocytes on blood film	Splenectomy should be avoided (see text)
	Decreased protein 7.2b (one subset)		Folic acid 1 mg qd
	Abnormal RBC cation and water content		
Paroxysmal nocturnal hemoglobinuria	Primary acquired marrow disorder	Ham's test, sucrosis lysis test	Folic acid 1 mg qd
	RBCs unusually sensitive to complement-mediated lysis	Marrow aspirate and biopsy to assess cellularity	Mild cytopenias–no treatment
		Decreased decay accelerating factor	Chronic hemolysis and other cytopenias–prednisone, 60 mg qd initially, then taper if possible; chronic 15–40 mg qod
		Decreased WBC, CD55, and CD59 or decreased RBC CD59 by flow cytometry	
			Iron for secondary iron deficiency
			Androgens–fluoxymesterone, danazol
			Anticoagulation
			Marrow transplant for pancytopenia
Enzyme Deficiencies			
Pyruvate kinase deficiency	Decreased or abnormal enzyme	PK assay—decreased max or rarely high Km variant	If severe anemia with symptoms, poor growth and age < 2 yr–transfusion
			Splenectomy > age 6 yr but earlier if necessary
			Folic acid, 1 mg qd
G6PD deficiency	A type: age-labile enzyme	Glucose-6-phosphate dehydrogenase	Avoid oxidant stress to RBCs
	Mediterranean type: no enzyme activity in circulating RBCs		Transfusion if acute anemia is symptomatic
Hemoglobin Abnormalities (For discussion of hemoglobinopathies, see sections on these topics)			
Extracellular Defects			
Autoimmune			

Autoimmune hemolytic anemia "Warm" antibody	Alteration in membrane surface antigen (Rh) or abnormal response of B lymphocytes, causing autoantibody formation	Spherocytes on blood film	If Hb > 10 g/dL + retic <10%–none
		Positive direct Coombs test to IgG "warm" antibody directed against RBCs	Severe anemia may require transfusion
			Prednisone, 2 mg/kg/24 hr
		Positive indirect Coombs test and antibody detectable in plasma	IVIG
			Danazol
		Thermal amplitude 35–40°C	Splenectomy
		Some complement (C3b) may be detected on RBCs	Immunosuppressives
			Folic acid 1 mg/24 hr if chronic
		Tests for underlying disease	
"Cold" antibody	"Cold" or IgM autoantibody directed against I/i antigen system	Agglutination or rouleaux on blood film	If Hb >10 g/dL + retic <10%–none
		Positive direct Coombs test to complement (C3b)	Severe anemia may require transfusion
			Avoid exposure to cold
		Tests for underlying disease	If severe: immunosuppressives and plasmapheresis
		Serology for infectious mononucleosis; anti-i present	Prednisone–*less* effective
			Splenectomy–*not* useful
		Serology for *Mycoplasma pneumoniae*; anti-I present	Folic acid, 1 mg/24 hr if chronic
Fragmentation Hemolysis			
DIC, TTP, HUS	Direct damage to RBC membrane	Fragments on blood film	Treat underlying condition
			Transfusion: but transfused cells also will have shortened life span
Extracorporeal membrane oxygenation	Direct damage to RBC membrane	Fragments on blood film	Supportive
			Transfusion until ECMO discontinued
Prosthetic heart valve	Direct damage to RBC membrane	Fragments on blood film	Folic acid, 1 mg/24 hr
			Iron for secondary iron deficiency
Burns—thermal injury	Direct damage to RBC membrane	Spherocytes on blood film	Supportive
			Transfusion
Hypersplenism	Effects of sequestration, pH, lipases and other enzymes, and macrophages on RBCs	Thrombocytopenia and neutropenia	Treat underlying condition—cytopenias usually mild
			Splenectomy if complicating other anemia (e.g., thalassemia major)
			Folic acid, 1 mg/24 hr
Plasma Factors			

Liver disease	Alteration in plasma cholesterol and phospholipids	Target cells or spiculated RBCs on blood film	Treat underlying condition
			Transfusion: but transfused cells also will have shortened life span
		Abnormal liver function tests	
			Folic acid, 1 mg/24 hr
Abetalipoproteinemia	Absence of apolipoprotein ß	Acanthocytes on blood film	Vitamin E (A, K, and D)
	Vitamin E deficiency and heightened sensitivity to oxidative damage	Absent chylomicrons, VLDL and LDL	Folic acid, 1 mg/24 hr
			Dietary restriction of triglycerides
Infections	Toxic effects on RBCs	Associated symptoms and signs	Antibiotics
		Cultures	Supportive
Wilson disease	Effect of copper on RBC membrane, usually self-limited	Spherocytes on blood film	Penicillamine
		Copper, ceruloplasmin	Supportive
		Penicillamine challenge and urine copper excretion	Transfusion if acute anemia is symptomatic

ECMO = extracorporeal membrane oxygenation; retic = reticulocyte count; DIC = disseminated intravascular coagulation; TTP = thrombotic thrombocytopenic purpura; HUS = hemolytic-uremic syndrome; VLDL = very low density lipoproteins; LDL = low density lipoproteins; IVIG = intravenous immunoglobin; RBC = red blood cell; Hb = hemoglobin.

Chapter 450 - Hereditary Spherocytosis

George B. Segel

Hereditary spherocytosis is a common cause of hemolysis and hemolytic anemia, with a prevalence of approximately 1/5,000 in people of Northern European extraction. It is the most common familial and congenital abnormality of the red blood cell (RBC) membrane. Affected individuals may be asymptomatic without anemia and with minimal hemolysis or may have a severe hemolytic anemia. Hereditary spherocytosis has been described in most ethnic groups but is most common among persons of Northern European origin.

Etiology.

Hereditary spherocytosis usually is transmitted as an autosomal dominant and, less frequently, as an autosomal recessive disorder. As many as 25% of patients have no previous family history. Of these patients, most represent new mutations, and a few result from recessive inheritance or represent non-paternity. The most common molecular defects are abnormalities of spectrin or ankyrin, which are major components of the cytoskeleton responsible for RBC shape. A recessive defect has been described in a-spectrin; dominant defects, in ß-spectrin and in protein 3; and dominant and recessive defects, in ankyrin. A deficiency in spectrin, protein 3, or ankyrin results in uncoupling in the "vertical" interactions of the lipid bilayer skeleton and the loss of membrane microvesicles (Fig. 450–1). The loss of membrane surface area without a proportional loss of volume causes sphering of the RBCs and an associated increase in cation permeability, cation transport, adenosine triphosphate utilization, and glycolysis. The decreased deformability of the spherocytic RBCs impairs cell passage from the splenic cords to the splenic sinuses, and the spherocytic RBCs are destroyed prematurely in the spleen. Splenectomy markedly improves the RBC life span and cures the anemia.

Clinical Manifestations.

Hereditary spherocytosis may be a cause of hemolytic disease in the newborn and may present as anemia and hyperbilirubinemia sufficiently severe to require phototherapy or exchange transfusions. The severity in infants and children is variable. Some children remain asymptomatic into adulthood, but others may have severe anemia with pallor, jaundice, fatigue, and exercise intolerance. Severe cases may be marked by expansion of the diploë of the skull and the medullary region of other bones, but to a lesser extent than in thalassemia major. After infancy, the spleen is usually enlarged, and pigmentary (bilirubin) gallstones may form as early as age 4–5 yr. At least 50% of unsplenectomized patients ultimately form gallstones, although for the most part they remain asymptomatic. Because of the high RBC turnover and heightened erythroid marrow activity, children with hereditary spherocytosis are susceptible to aplastic crisis, primarily as a result of parvovirus infection, and to hypoplastic crises associated with various other infections. Such erythroid marrow failure may result rapidly in profound anemia (hematocrit

Figure 450-1 Vertical and horizontal interactions of membrane proteins and the pathobiology of the red cell lesion in hereditary spherocytosis (HS) and hereditary elliptocytosis/hereditary pyropoikilocytosis (HE/HPP). *Left*, A defect of vertical or transverse interactions as exemplified by the red cell membrane lesion in HS. Partial deficiencies of spectrin, ankyrin (band 2.1), or band 3 protein lead to uncoupling of the membrane lipid bilayer from the underlying skeleton *(arrow)* followed by a formation of spectrin-free microvesicles of 0.2–0.5?µm in diameter *(arrowheads)*. These vesicles can be visualized by transmission electron microscopy, but they are not seen during examination of blood films. The subsequent loss of cell surface and a decrease in the surface/volume ratio leads to spherocytosis. *Right*, Defect of horizontal or parallel interactions of skeletal proteins as exemplified by the membrane lesion in hemolytic forms of HE associated with a defect of spectrin heterodimer self-association. The molecular lesion involving a weakened self-association of spectrin heterodimers to tetramers represents a horizontal defect of the stress-supporting protein interactions. It leads to a disruption of the membrane skeletal lattice and, consequently, whole cell destabilization followed by red cell fragmentation and poikilocytosis. Such fragments are readily seen on stained blood films. (Modified from Palek J, Jarolim P: Clinical expression and laboratory detection of red blood cell membrane protein mutations. *Semin Hematol* 1993;30:249.)

<10%), high-output heart failure, hypoxia, cardiovascular collapse, and death.

Laboratory Findings.

Evidence for hemolysis includes reticulocytosis and indirect hyperbilirubinemia. The hemoglobin level usually is 6–10?g/dL, but it can be in the normal range. The reticulocyte percentage often is heightened to 6–20%, with a mean of approximately 10%. The mean corpuscular volume is normal, whereas the mean corpuscular hemoglobin concentration often is increased (36–38?g/dL RBCs). The RBCs on the blood film vary in size and include polychromatophilic reticulocytes and spherocytes (Fig. 450–2*A*). The spherocytes are smaller in diameter and on the blood film are hyperchromic as a result of the high hemoglobin concentration. The central pallor is less conspicuous than in normal cells. Spherocytes may be the predominant cell or may be relatively sparse, depending on severity of the disease, but they usually account for more than 15–20% of the cells when hemolytic anemia is present. Erythroid hyperplasia is evident in the marrow aspirate or biopsy. The marrow expansion may be evident on routine roentgenographic examination. Other evidence of hemolysis may include decreased haptoglobin and the presence of gallstones by ultrasonography.

Figure 450-2 Morphology of abnormal red cells. *A*, Hereditary spherocytosis; *B*, hereditary

elliptocytosis; *C*, hereditary pyropoikilocytosis; *D*, hereditary stomatocytosis; *E*, acanthocytosis; *F*, fragmentation hemolysis.

The *diagnosis* of hereditary spherocytosis usually is established clinically from the blood film, showing many spherocytes and reticulocytes, from the family history, and from splenomegaly. The presence of spherocytes in the blood can be confirmed with an osmotic fragility test. The RBCs are incubated in progressive dilutions of an iso-osmotic buffered salt solution. Exposure to hypotonic saline causes RBCs to swell, and the spherocytes lyse more readily than biconcave cells in hypotonic solutions. This feature is accentuated by depriving the cells of glucose overnight at 37℃, a so-called incubated osmotic fragility test.

As a research tool, the specific protein abnormality can be established in 80% of these patients by RBC membrane protein analysis using gel electrophoresis and densitometric quantitation. The protein abnormalities are more evident in patients who have had a splenectomy. Studies to define the underlying defects in the cytoskeleton may require assessment of protein synthesis, stability, assembly, and binding to the other membrane proteins. Molecular diagnosis also is possible. Most patients have family-specific private mutations that can be detected by DNA analysis. De novo mutations in the ß-spectrin and ankyrin genes have been described in 50% of patients with unaffected parents.

Differential Diagnosis.

The major alternative considerations when large numbers of spherocytes are seen on the blood film are isoimmune or autoimmune hemolysis. Isoimmune hemolytic disease of the newborn, particularly due to ABO incompatibility, mimics hereditary spherocytosis. The detection of antibody on an infant's RBCs using a direct antiglobulin (Coombs) test should establish the diagnosis of immune hemolysis. Autoimmune hemolytic anemias also are characterized by spherocytes, and there may be evidence of a previously normal hemoglobin, hematocrit, and reticulocyte count. Rare causes of spherocytosis include thermal injury, clostridial septicemia with exotoxemia, and Wilson disease, each of which may present as a transient hemolytic anemia (see Table 449–1).

Treatment.

Because the spherocytes in hereditary spherocytosis are destroyed almost exclusively in the spleen, splenectomy eliminates most of the hemolysis associated with this disorder. After splenectomy, osmotic fragility often improves because of diminished splenic conditioning and less RBC membrane loss, and the anemia, reticulocytosis, and hyperbilirubinemia resolve. Whether all patients with hereditary spherocytosis should undergo splenectomy is controversial. Some hematologists do not recommend splenectomy for those patients whose hemoglobin values exceed 10?g/dL and whose reticulocyte percentage is less than 10. Folic acid, 1?mg/24?hr, should be administered to prevent secondary folic acid deficiency. For patients with more severe anemia and reticulocytosis or those with hypoplastic or aplastic crises, poor growth, or cardiomegaly, splenectomy is recommended after age 5–6 yr to avoid the heightened risk of postsplenectomy sepsis in younger children. The introduction of laparoscopic splenectomy decreases the length of hospital stay and has replaced open splenectomy for many patients. Vaccines for encapsulated organisms such as pneumococcus, meningococcus, and *Haemophilus influenzae* type b should be administered before splenectomy, and oral prophylactic penicillin V (age <5 yr: 125?mg twice daily; age =5 yr through adulthood: 250?mg twice daily) administered thereafter. Postsplenectomy thrombocytosis is commonly observed but needs no treatment and usually resolves spontaneously. Partial splenectomy also may be useful in children younger than age 5 yr and can provide some increase in hemoglobin and reduction in the reticulocyte count, with potential maintenance of splenic phagocytic and immune function.

Chapter 451 - Hereditary Elliptocytosis

George B. Segel

Hereditary elliptocytosis is an uncommon disorder that varies markedly in severity. Mild hereditary elliptocytosis produces no symptoms, but more severe varieties may result in neonatal poikilocytosis (shape variation) and hemolysis, chronic or sporadic hemolytic anemias, or hereditary pyropoikilocytosis (HPP), which is a severe disorder with microspherocytosis and poikilocytosis. Although hereditary elliptocytosis is rare in Western populations, it is more commonly found in West Africa, where the abnormalities (spectrin mutations) may provide resistance to malarial infection.

Etiology.

Hereditary elliptocytosis is inherited as a dominant disorder. In the rare instances when two abnormal alleles are inherited (HPP), the patient exhibits a particularly severe hemolytic anemia. Various molecular defects have been described in hereditary elliptocytosis; these produce abnormalities of a- and ß-spectrin and defective spectrin heterodimer self-association (see Fig. 450–1). Such defects in the horizontal protein interactions result in gross membrane fragmentation, particularly in homozygous HPP. Less commonly, mutations in protein 4.1 and glycophorin C may produce elliptocytosis.

Clinical Manifestations.

Elliptocytosis may be noted as an incidental finding on a blood film examination and may not be associated with clinically significant hemolysis (see Fig. 450–2*B*). The diagnosis of hereditary elliptocytosis is established by the findings on the blood film, the autosomal dominant inheritance pattern, and the absence of other causes of elliptocytosis, such as deficiencies of iron, folic acid, or vitamin B_{12} . Hemolytic elliptocytosis may produce neonatal jaundice, even though characteristic elliptocytosis may not be evident at that time. The blood of the affected newborn may show bizarre poikilocytes and pyknocytes. The usual features of a chronic hemolytic process with elliptocytosis are manifested later as anemia, jaundice, splenomegaly, and osseous changes. Cholelithiasis may occur in later childhood, and aplastic crises have been reported. The most severe form is HPP, which is characterized by extreme microcytosis (mean corpuscular volume 50–60?fL/cell), extraordinary variation in the cell size and shape, and primarily microspherocytic rather than elliptocytic cells (see Fig. 450–2*C*). These patients inherit a mutant spectrin from one parent, who has mild or no elliptocytosis, and a partial spectrin deficiency from the other parent, who is hematologically normal.

Ovalocytes, in contrast to elliptocytes, are less elongated and may reflect a condition termed *Southeast Asian ovalocytosis* (SAO). SAO is associated with an abnormal protein 3, which functions as an anion exchanger. This disorder may produce augmented neonatal hyperbilirubinemia but causes little hemolysis later and may offer protection against *Plasmodium falciparum* malaria. This anion exchanger also is expressed in renal tubular cells and may cause distal renal tubular acidosis in association with SAO.

Laboratory Findings.

The blood film is the most important test to establish hereditary elliptocytosis (see Fig. 450–2*B*). The red blood cells (RBCs) show various degrees of elongation and may actually be rod shaped. In hereditary elliptocytosis, other abnormal RBC shapes may be present, depending on the severity of hemolysis. They include microcytes, spherocytes, and other poikilocytes. The reticulocyte percentage reflects the severity of hemolysis, and erythroid hyperplasia and indirect hyperbilirubinemia may be present. Increased thermal instability is characteristic of HPP, hence its name. The abnormal spectrin denatures and the cells lyse at 45–46°C instead of the usual 49–50°C. The specific protein abnormality can be established by protein separation and analysis techniques. Molecular defects currently are defined only in research laboratories.

Treatment.

If hereditary elliptocytosis represents a morphologic abnormality on the blood film without evident hemolysis, no treatment is necessary. Patients with chronic hemolysis should receive folic acid, 1?mg/24?hr, to prevent secondary folic acid deficiency. Splenectomy decreases the hemolysis and should be considered if the hemoglobin is less than 10?g/dL and the reticulocyte count is greater than 10%. The RBCs on the blood film may be more abnormal after splenectomy even though hemoglobin increases and the reticulocytes decrease. The hematologic features of SAO do not require treatment beyond the newborn period.

Chapter 452 - Hereditary Stomatocytosis

George B. Segel

Hereditary stomatocytosis is a rare condition in which the red blood cells (RBCs) are cup shaped. On stained blood film, they present a mouthlike slit in place of the usual circular area of central pallor (see Fig. 450–2*D*). Acquired stomatocytosis may be seen in several conditions, especially liver disease. Hereditary stomatocytosis is associated with increased RBC membrane permeability to Na^+ and K^+ and alterations in RBC hydration status. Dehydrated hereditary stomatocytosis is the most common type, but it is heterogeneous and sometimes is associated with pseudohyperkalemia from heightened RBC K^+ leak, particularly when the blood is cooled to room temperature, or it may be associated with a syndrome of perinatal edema and ascites. The perinatal edema syndrome is transient and remains unexplained. The hydrocytic or overhydrated variety is associated with abnormalities within the region of protein 7.2, or “stomatin,” which has been mapped to chromosome 9. A defective transcription promoter results in stomatin reduction, which may impair regulation of cation transport. Hemolytic anemia may be associated with hereditary stomatocytosis, but splenectomy is not a recommended treatment. Persistent symptomatic thrombocytosis may follow splenectomy if the hemolysis is not eliminated or markedly decreased. Patients have developed a life-threatening tendency toward in situ thrombosis after splenectomy in association with the abnormal adherence of the stomatocytic RBC to vascular endothelium in conjunction with the thrombocytosis.

Chapter 453 - Other Membrane Defects

George B. Segel

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Etiology.

Paroxysmal nocturnal hemoglobinuria (PNH) reflects an abnormality of marrow stem cells that affects many blood cell lines. The disease is not inherited; it is an acquired disorder of hematopoiesis characterized by a defect in proteins of the cell membrane that renders the red blood cells (RBCs) (and other cells) susceptible to damage by serum complement. The

deficient membrane-associated proteins include decay-accelerating factor, the C8 binding protein, and other proteins that normally impede complement lysis at various steps. The underlying defect involves the glycolipid anchor that maintains these proteins on the cell surface. Various mutations in the *PIGA* gene involved in glycosylphosphatidylinositol biosynthesis have been identified in patients with PNH. More than one *PIGA* mutation often occurs in an individual patient, suggesting multiclonality. Furthermore, glycosylphosphatidylinositol-deficient cells are found at low frequency in normal persons. This suggests that injury to the normal marrow stem cells provides a selective advantage to the PNH clones in the genesis of this disease.

Clinical Manifestations.

PNH is a rare disorder, particularly in children, but 26 patients with a mean age of 13 yr (0.8–21.4 yr) were diagnosed at Duke University Medical Center between 1966 and 1991. Approximately 60% of these patients presented with marrow failure, and the remainder had either intermittent or chronic anemia, often with prominent intravascular hemolysis. Nocturnal and morning hemoglobinuria is a classic finding in adults if hemolysis is worse during sleep. However, chronic hemolysis is more common in PNH despite its name. In addition to chronic hemolysis, thrombocytopenia and leukopenia are often characteristic. Thrombosis and

thromboembolic phenomena are serious complications that may be related to altered glycoproteins on the platelet surface and resultant platelet activation. Abdominal, back, and head pain may be prominent complaints. Hypoplastic or aplastic pancytopenia may precede or follow the onset of PNH, and rarely PNH progresses to acute myelogenous leukemia. The mortality in PNH is related primarily to the development of aplastic anemia or thrombotic complications. The predicted survival for children is 80% for 5 yr, 60% for 10 yr, and 28% for 20 yr.

Laboratory Findings.

The diagnosis of PNH was established classically by a positive result in either the acidified serum hemolysis (Ham) test or the sucrose lysis test, which activate the alternative and classic pathways of complement lysis, respectively. Hemosiderinuria is common and reflects the chronic intravascular hemolysis. Markedly reduced levels of RBC acetylcholinesterase activity and reduced levels of decay-accelerating factor also are found. Flow cytometry now is the best diagnostic test for PNH. With the use of anti-CD59 for RBCs and anti-CD55 and anti-CD59 for granulocytes, flow cytometry is more sensitive than the classic RBC lysis tests in detecting the reduced glycolipid-bound membrane proteins. Newer reagents, such as fluorescent aerolysin, may heighten the sensitivity of detection by binding selectively to glycosylphosphatidylinositol anchors.

Treatment.

Splenectomy is not indicated. Glucocorticoids such as prednisone (2?mg/kg/24?hr) have been used to treat acute hemolytic episodes, and their dosage should be tapered as soon as the hemolysis abates. Prolonged anticoagulation therapy may be of benefit when thromboses occur, and heparin and low molecular heparin may inhibit complement-mediated hemolysis. Because of chronic loss of iron as hemosiderin in the urine, iron therapy may be necessary. Androgens, such as fluoxymesterone (Halotestin) and danazol, antithymocyte globulin, cyclosporine, and growth factors, such as erythropoietin and granulocyte colony-stimulating factor, have been used to treat marrow failure. Bone marrow transplantation has been successful in treating some cases, and nonmyeloablative transplantation may reduce transplant-related mortality and morbidity. Retroviral gene transfer of *PIGA* restores the glycolipid anchor in cultured cells and may be the basis for future gene therapy.

ACANTHOCYTOSIS

Acanthocytosis is characterized by RBCs with irregular circumferential pointed projections (see Fig. 450–2*E*). This morphologic finding is seen with alterations in the cholesterol/ phospholipid ratio in some patients with liver disease and in congenital abetalipoproteinemia associated with malabsorption, neuromuscular abnormalities, and retinitis pigmentosa (see Chapters 75.3 and 320.12). It also is associated with the rare X-linked *McLeod syndrome*: absence of the Kx (Kell) antigen, late-onset myopathy, neurologic abnormalities such as chorea, splenomegaly, and hemolysis with acanthocytosis.

Chapter 454 - Hemoglobin Disorders

Keith Quirolo
Elliott Vichinsky

Point mutations and deletions in the hemoglobin genes result in structural changes in the hemoglobin molecule leading to a change in function. The globin genes are found in clusters on chromosomes 11 (ß globins) and 16 (a globins) as at least six conserved, duplicated genes. Their control is complex, including an upstream locus control region as well as an X-linked control site. It is likely that fetal and adult non-a genes are present in a single cluster. The order of the genes on the chromosomes follows ontogeny. The a- and ß-gene clusters are translated and the globin molecules combine to form the embryonic hemoglobins: Gower-1 ($?_2$ e_2), Gower-2 (a_2 e_2), and Portland ($?_2$ $?_2$). Embryonic hemoglobins are not found in the circulation after 8 wk of gestational age, and by 9 wk gestational age the major hemoglobin is Hb F (a_2 $?_2$). In the normal individual, Hb A (a_2 $ß_2$) appears in the first month of gestation but does not become the dominant hemoglobin until after birth. Hb A_2 (a_2 d_2) appears shortly before birth and remains at a low level throughout adult life. (Also see Chapter 438 .)

Hemoglobin disorders can be functionally classified as noted in Table 454–1 . The functionality of the altered hemoglobin can

TABLE 454-1 -- **Functional Classification of Hemoglobins**

Functional Abnormality of Hemoglobin	Location of Substitution	Clinical Abnormality	Example Hemoglobin
None	Surface	None	G Philadelphia
Aggregation	Surface	Hemolytic anemia	S
Unstable	Internal	Hemolytic anemia	Köln

Increased O_2 affinity	a_1 ß$_2$ Contact or ßCterminal	Erythrocytosis	Chesapeake
Decreased O_2 affinity	Near heme a_1 ß$_2$ contact	Cyanosis	Kansas
Methemoglobinemia	Proximal or distal histidine	Cyanosis	M
a-Thalassemia	Variable	Hemolytic anemia	Constant Spring
ß-Thalassemia	Variable	Hemolytic anemia	Lepore

be predicted to some degree by the site of the mutation. Those in the heme pocket region will affect oxygen affinity, and those in the periphery will affect the behavior of the hemoglobin, as can be seen in the table. Some hematologists refer to qualitative (structural abnormalities, i.e., sickle hemoglobins) and quantitative (hemoglobin production, i.e., thalassemias, hemolytic anemias) abnormalities to be more concise.

THE HEMOGLOBINOPATHIES

There are approximately 700 variant hemoglobins; the majority are the result of point mutations (634), and the rest are two amino acid substitutions, deletions or insertions, extended chains, and fusions. The majority of these hemoglobin variants are extremely rare. Those variants that are caused by the evolutionary pressures of malaria are the most prevalent worldwide and are a major public health challenge owing to improvements in health care leading to a much longer life expectancy for affected individuals. The diagnosis of the common inherited hemoglobinopathies can be made by newborn screening programs, which should improve access to appropriate medical care.

454.1 Sickle Cell Disease

Epidemiology.

Sickle cell disease has been recognized in the malarial areas of the world for millennia but has only been recognized by the western scientific community since the description of “sickled” red cells in 1910 by Herrick. In malarial areas there is a selective advantage to the heterozygote (Hb AS), although the actual mechanism of this advantage is not known. Individuals with sickle cell trait have lower levels of *Plasmodium falciparum* parasitemia, higher hemoglobin counts, and less severe reinfections than individuals with homozygous Hb A. In these areas there are confounding factors that influence resistance to malaria, including the Duffy chemokine receptor, glucose-6-phosphate dehydrogenase, and HLA-B53 and HLA-DRB1*1302. Sickle cell disease occurs in endemic malarial areas, including North Africa, Italy, Greece, Central India, and most predominantly in sub-Saharan Africa. Because of the slave trade, sickle cell disease is also common in North, Central, and South America as well as the Caribbean. Sickle cell disease is most common in individuals of African descent but is seen in Hispanics, Arabians, Indians, and whites. In the United States the incidence is 1 in 625 live births to African-Americans. The severity of sickle cell disease is somewhat influenced by haplotypes specific to areas of origin of the Hb S mutation: Senegal, Benin, Bantu, and Asian.

Pathophysiology.

Hb S is the result of a single base-pair change, thymine for adenine, at the sixth codon of the ß gene. This change encodes valine instead of glutamine in the sixth position on the ß-globin molecule. The charge at this site is altered and allows for polymerization of hemoglobin under conditions of hypoxia. Acidosis, hemoglobin concentration, and the combination of Hb S with other hemoglobins affect the ability of Hb S to polymerize. Oxygen affinity is affected by 2,3-diphosphoglycerate (2,3-DPG) and pH; an increase in 2,3-DPG and a decrease in pH increase polymerization. Hemoglobin concentration has a lesser effect, a higher concentration leading to increased polymerization. The effect of other hemoglobins depends on the extent of their homology with Hb S; in descending order of ability to copolymerize are hemoglobins S, C, D, O Arab, A, J, and F. Based on the effect of other hemoglobins, intracellular pH, and mean corpuscular hemoglobin concentration on polymerization, new therapies for sickle cell disease can be hypothesized. Because of the disruption of the red cell membrane, the increased adhesiveness of sickle reticulocytes, and the increased leukocyte count there is a thrombotic coagulopathy associated with sickle cell anemia that contributes to the severity of the disease.

Sickle Cell Anemia (Homozygous Hemoglobin S or S ß^0 -thalassemia)

Children who have only hemoglobin S usually have a lifetime of severe intermittent illness, with painful vaso-occlusive episodes and eventually the sequelae of complications of their sickle cell disease (Table 454–2). A few children will have a less severe course, owing to higher levels of Hb F.

Clinical Manifestations.

Affected newborns seldom exhibit clinical features of sickle cell disease; hemolytic anemia gradually develops over the first 2–4 mo, paralleling the replacement of much of the fetal hemoglobin by Hb S. Other clinical manifestations are uncommon before 5–6 mo of age. However, infants with sickle cell anemia have abnormal immune function and by about 6 mo of age many will have functional asplenia, making bacterial sepsis the greatest risk for morbidity and mortality. By the age of 5 yr, 95% of children with sickle cell anemia will have functional asplenia. Acute sickle dactylitis, presenting as the *hand-foot syndrome*, is frequently the first overt evidence that sickle cell disease is present in an infant. Dactylitis in infants requires medical attention for hydration and pain management. Its associated findings include painful, usually symmetric, swelling of the hands and feet. The underlying abnormality is ischemic necrosis of the small bones, believed to be caused by a choking off of the blood supply as a result of the rapidly expanding bone marrow. Roentgenograms are not informative in the acute phase of dactylitis but later show evidence of extensive bony destruction and repair (Fig. 454–1). Predictors of a severe course of sickle cell disease are anemia, painful episodes, and dactylitis before the age of 24 mo.

TABLE 454.1-2 -- Complications of Sickle Cell Disease

Acute painful episodes represent the most frequent and prominent manifestation of sickle cell disease. Most patients experience some pain on a nearly daily basis. Episodes of severe pain that require hospitalization and parenteral analgesic administration average about one per year in children with Hb SS, but this interval varies considerably. Some patients never experience severe pain, and others require hospital admission with such frequency that they become seriously disabled. In young children, pain often involves the extremities; in older patients, pain in the head, chest, abdomen, and back occurs more commonly. In an individual patient, pain tends to recur in a limited number of sites. Intercurrent illnesses accompanied by fever, hypoxia, and acidosis, all of which promote the deoxygenation of Hb S, may precipitate sickle pain episodes, but acute pain also develops frequently without an apparent antecedent event. Sickle-related abdominal pain may mimic that of an acute surgical condition.

More extensive vaso-occlusive events in children can produce gross ischemic damage. Acute pain episodes may progress to infarction of bone marrow or bone. Splenic infarcts are common in children, causing pain and contributing to the process of "autosplenectomy." Pulmonary infarction, often occurring in association with pneumonitis or microscopic fat emboli (from bone marrow infarction), may produce the severe clinical picture of *acute chest syndrome*. Strokes caused by cerebrovascular occlusion are among the most catastrophic acute events and are a frequent cause of hemiplegia. As many as 10% of children with sickle cell anemia, mainly preadolescent and older patients, exhibit sequelae of cerebrovascular occlusion. Findings of increased blood flow velocity by transcranial Doppler studies may be predictive of increased risk of stroke in these patients, and this may help to identify children who will benefit from preventive therapy. Ischemic damage may also affect the myocardium, liver, and kidneys. Renal function is progressively impaired by diffuse glomerular and tubular fibrosis, and hyposthenuria accompanied by polyuria is a characteristic finding in patients older than 5 yr. Renal papillary necrosis and nephrotic syndrome also develop occasionally. *Priapism* is a relatively frequent complication that results from the pooling of blood in the corpora cavernosa, causing obstruction of the venous outflow.

In the first 5 yr of life common complications of sickle cell disease include bacterial sepsis, splenic or hepatic sequestration, acute chest syndrome, parvovirus B19 infection, and vaso-occlusive episodes. Occasionally, children will have priapism, stroke, and chronic splenic sequestration with severe chronic anemia (Fig. 454–2A). Urinary tract infections are more

common and can lead to bacteremia. Viral pneumonia and reactive airways disease can rapidly become acute chest syndrome. Acute splenic sequestration has a peak incidence between 6 mo and 3 yr and can be rapid in onset and lead to death. The most common cause of mortality is sepsis and acute chest syndrome.

Young children with Hb SS may have splenic enlargement associated with their hemolytic disease, with progression to the syndrome of *hypersplenism* accompanied by worsening anemia and sometimes thrombocytopenia. *Acute splenic sequestration* is a distinct and episodic event that occurs in infants and young children with sickle cell anemia, often following an acute febrile illness. For unknown reasons, large amounts of blood become acutely pooled in the spleen, which becomes massively enlarged, and signs of circulatory collapse rapidly develop. Blood transfusions in the acute phase may be lifesaving. Altered splenic function in young children with sickle cell disease is a significant factor leading to their increased susceptibility to meningitis, sepsis, and other serious infections, mainly caused by pneumococci and

Haemophilus influenzae. In the absence of specific antibody to the polysaccharide capsular antigens of these organisms, splenic activity is essential for removing these bacteria when they invade the blood. Despite frequent enlargement of the spleen in young patients with Hb SS, its phagocytic and reticuloendothelial functions have been shown to be

markedly reduced. As an additional risk factor, children with sickle cell disease have also been shown to have deficient levels of serum opsonins, of the alternate complement pathway, against pneumococci. Children with sickle cell disease also have increased susceptibility to *Salmonella* osteomyelitis (partly because of bone necrosis).

As children become older they more frequently develop other complications of sickle cell anemia. Stroke is more common after the age of 5 yr, with the peak being between 6 and 9 yr. Children often begin to have more frequent vaso-occlusive episodes from 5–10 yr of age, and the episodes sometimes become more severe. Some children develop avascular necrosis of the hips; others develop cholelithiasis requiring cholecystectomy. *Salmonella* osteomyelitis may occur. With matriculation to school, affected children are exposed to more infectious agents, including parvovirus, which can cause a severe anemia characterized by the absence of reticulocytes during the anemic phase; blood transfusion is frequently required. Enuresis is a common sequela of sickle renal disease. Children with sickle cell anemia may develop school problems because of frequent absence; they begin to have fears related to their sickle cell disease and often fear death from their disease. There is growing evidence that there may be subtle, sickle cell–related brain injury in young children with sickle cell disease, with 25–30% of children suffering occult strokes.

Adolescents begin to develop some of the chronic changes of sickle cell disease. These children are still at risk for all of the complications of younger children. In addition, there is an increased incidence of urinary tract infection with bacteremia in young women and severe priapism in young men, leading to impotence. Frequent episodes of acute chest syndrome in early childhood may subsequently manifest as pulmonary hypertension. Hip pain in this age group may be the harbinger of avascular necrosis. Skin ulcers may also develop in adolescence and pose a chronic problem. Proteinuria is the first indication of sickle nephropathy; over 12% of adolescents will develop chronic renal disease. Retinopathy may develop in 3% of patients with sickle cell anemia but in 30% of those with Hb SC disease. Hyphema is a medical emergency in sickle cell disease. Stroke is still a risk in these young men and women.

Development must be monitored closely. By mid childhood most patients are underweight. Some adolescents have marked pubertal delay, although the majority of adolescents eventually develop normally. Zinc deficiency, which is prevalent in children with sickle cell disease, may contribute to their poor growth and delayed maturation. Coping can be extremely problematic for those adolescents who have had frequent hospitalizations, more than one chronic complication of sickle cell disease, or poor social support systems.

In common with patients having other forms of chronic hemolytic anemia, children with Hb SS are at risk of developing a rapid, potentially life-threatening decrease in their hemoglobin level (aplastic episodes) in association with parvovirus B19 infection (see Chapter 230). Cardiomegaly is invariably present in older children, often caused partly by sickle cell–related cardiomyopathy. Increased iron absorption contributes to parenchymal damage of the liver, pancreas, and heart. Symptomatic gallstone formation is common in adolescent and older patients, occasionally occurring in children as young as 5 yr.

Laboratory Findings.

Sickle cell disease should be suspected in all patients who have the clinical manifestations of sickle cell disease regardless of their ethnic origin (see Table 454–2). A complete blood cell count usually reveals an increased reticulocyte count (5–15%), upper limit of normal or greater leukocyte count (12,000–20,000/mm^3), normal mean corpuscular volume (MCV) (unless a thalassemic hemoglobin is present), mild to moderate anemia (5–9?g/dL), normal to increased platelet count, and a normal differential (or predominance of neutrophils); if severe anemia is present, nucleated red cells can be found. A diagnosis of sickle cell disease can be suspected by examination of the blood smear (see Fig. 454–2*A*) for target cells, poikilocytes, hypochromasia, sickle red cells, nucleated RBCs, and Howell-Jolly bodies and confirmed by hemoglobin electrophoresis or high-pressure liquid chromatography (HPLC). Bone marrow is markedly hyperplastic with erythroid predominance. If variant hemoglobins are present, only minor changes in the blood cell count may occur, and other diagnostic studies should be used for identification.

Radiologic studies may reveal characteristic bony findings of sickle cell disease in the vertebral bodies, mild expansion of the marrow cavities, osteoporosis, and possibly sclerosis of the long bones and femoral heads. Renal concentrating capacity is usually decreased.

Diagnosis.

In the United States, sickle cell disease is diagnosed in most states at birth through newborn screening programs (Table 454–3). These programs use hemoglobin electrophoresis or HPLC to define abnormal hemoglobins. Confirmatory studies for Hb S or variants are performed after birth. Newborn infants who have HbFS on screening could also have $Sd\beta^0$ -thalassemia or S-hereditary persistence of fetal hemoglobin (HPFH); some hemoglobin variants need to be defined by further diagnostic studies. Prenatal diagnosis is also possible for parents who both have sickle cell trait. Most African-Americans of reproductive age do not know their trait status; this is problematic because 1 of 14 African-Americans carries the trait. Hispanics and other peoples almost never know they are heterozygous for Hb S, Hb C, or thalassemia trait.

Differential Diagnosis.

The various clinical manifestations of sickle cell disease, including limb pain, heart murmurs, hepatosplenomegaly, and anemia, may suggest a number of other

diagnoses, including rheumatic fever or rheumatoid arthritis, osteomyelitis, and leukemia. In patients who have an Hb SS electrophoresis pattern and concomitant microcytosis (MCV < 78?fL), possibilities that require consideration include iron deficiency or a combination of Hb S with a- or $ß^0$ -thalassemia.

Treatment.

Treatment in sickle cell disease is directed toward the *prevention* of complications and optimization of health and healthy coping strategies. All children who have sickle cell disease should be immunized with the conjugate pneumococcal vaccine and all other routine vaccines of childhood. At the age of 2 mo all children should begin penicillin prophylaxis with 125?mg twice daily. It is extremely important that the physicians and the caretakers of these children understand the risks to children with this disease. Caretakers need to be taught how to take a reliable temperature, assess illness, palpate their child's spleen, and recognize the symptoms of anemia and stroke. Adequate medical care should be available and reliable. At the age of 3 yr the penicillin dose is increased to 250?mg twice a day. There is some controversy as to when to discontinue penicillin prophylaxis; some physicians discontinue this medication at 5 yr age,

TABLE 454.1-3 -- **Newborn Screening for Hemoglobinopathy**

FABart's	a-Thalassemia

others later. Because of the thrombotic nature of the sickle hemoglobins and the high red cell turnover, folate supplementation is recommended as well.

Although there have been reports of outpatient management of *febrile infants* older than the age of 6 mo, this approach is not recommended. After the age of 18 to 24 mo, outpatient treatment may be considered if the treating physician knows the patients well, there is the ability to return to the hospital for follow-up, and the treating physician and parent believe the child is well enough for outpatient management of a febrile illness. In this situation, a thorough examination be performed; a blood cell count, blood culture, urine culture, and chest radiograph obtained; and ceftriaxone administered. Children with any physical findings, high fever or previous episodes of sepsis, or splenectomy should be hospitalized.

Treatment of *pain* in children with sickle cell disease requires patience and attention to detail (also see Chapters 38 and 66). Children may begin having painful episodes at a young age, and their caretakers must be taught how to treat this symptom and when to seek medical assistance. Limited amounts of opiate medication should be prescribed (usually acetaminophen with codeine) to avoid masking disease with opiates and to ensure that the child will be evaluated if a painful event is long lasting. Day treatment center care may avoid hospitalization, which is frequently necessary. Children older than the age of 7–10 yr may be able to use a patient-controlled analgesia (PCA) pump. A nonsteroidal anti-inflammatory drug and opiate medication should be instituted together. The opiate medication should be weaned after 3–4 days in most cases. Patients may have withdrawal symptoms if opiates are abruptly withdrawn. A cause should be sought for pain symptoms, and patients should be monitored for other complications of sickle cell disease and treated expectantly.

Blood transfusion is indicated for acute chest syndrome, stroke, stroke prevention, severe anemia, and splenic sequestration and before general surgery. In some patients, transfusion may be instituted for chronic pain syndromes, if accompanied by psychotherapy to enhance coping strategy. Blood transfusions usually do not reverse ischemic damage but do prevent most of the manifestations of sickle cell disease. Even while on chronic transfusion therapy children can still have transient cerebral ischemia as well as avascular necrosis of the hips and shoulders.

Children who have Hb SS or $Sß^0$ -thalassemia have the highest risk of stroke and should be monitored for risk of stroke with transcranial Doppler (TCD) as recommended by the STOP study. This should be done at a sickle cell center under the direction of a physician familiar with sickle cell disease, transfusion therapy, and monitoring for stroke and complications of transfusion. Increased blood flow velocity in the cerebral arteries (> 200?cm/sec) diagnosed by TCD is an indication for initiation of transfusions to maintain Hb S below 30%. All children who have sickle cell disease should have a red cell phenotype determination in infancy and receive partially phenotypically matched (for C, E, and Kell at least), leukocyte-depleted red cell products.

Drug therapy with hydroxyurea has successfully elevated fetal hemoglobin levels and reduced morbidity in adults with sickle cell anemia. There have been several encouraging studies of hydroxyurea therapy in children. One study did not detect adverse effects on height, weight gain, or pubertal development. However, there are no large, randomized studies of efficacy and long-term safety when hydroxyurea is used in children. Children with sickle cell complications (see Table 454–2) are usually begun on hydroxyurea at 15?mg/kg/24?hr, and, if tolerated, the dose is gradually increased to a maximum of less than 30?mg/kg/24?hr. Complete blood cell counts, liver function tests, and fetal hemoglobin levels are monitored at least monthly as long as patients are on this medication. An increase in MCV of over 100?fL/dL, a decrease in the leukocyte count to low normal, and an increase in fetal

hemoglobin is an indication of compliance and of efficacy. The increase in fetal hemoglobin is variable but is usually between 10–25%. The fetal hemoglobin is not uniformly distributed in the red cells but appears in clones of F cells. There is a reduction in severity of disease in children who have only moderate increases in fetal hemoglobin. Other medical therapies are now in clinical trials.

Bone marrow transplantation is the only cure for sickle cell disease, but it is only an option for children younger than 16 yr of age who have an HLA-matched sibling. An initial problem of increased neurologic complications during transplantation has been minimized by improved transplantation regimens. There is a 5% mortality rate. An innovative method of transplant referred to as a nonmyeloablative regimen has been used in a few patients. This technique induces a stable stem cell chimera with phenotypic overexpression of the healthy graft resulting in an asymptomatic patient. This regimen does not cause the significant myelosuppression or immune deficiency observed in full transplant protocols. Long-term stability of the chimera graft needs to be proven before this technique is accepted.

Other experimental treatments are aimed at increasing intracellular hydration, decreasing red cell adhesion, lowering blood viscosity, elevating nitric oxide levels, and decreasing thrombosis. Combination therapy of different treatment modalities appears likely in the future.

Other Sickle Cell Syndromes.

The most commonly occurring sickle syndromes besides Hb SS are Hb SC and $Sß^0$ -thalassemia and $Sß^+$ -thalassemia. The other syndromes—SD, SO, Arab, and other variants—are much less common. $Sß^0$ -thalassemia is a severe sickle cell anemia. Hb SC does not polymerize like Hb SS, but the presence of crystals of Hb C interact with the membrane ion transport dehydrating the cell, inducing sickling. Children who have Hb SC disease can experience the same symptoms and complications as those with severe Hb SS disease, but the frequency is less. These children have an increased hemoglobin concentration and better growth. However, they have more fat in their bone marrow, and this can lead to more severe acute chest syndrome and organ failure caused by fat emboli from bone necrosis. There is also an increased incidence of retinopathy and chronic hypersplenism. Despite a well-developed appearance, these children may develop all the chronic complications of sickle cell disease. $Sß^+$ -thalassemia is a less severe form of sickle cell disease with a much lower frequency of the severe manifestations.

454.2 Sickle Cell Trait (Hemoglobin AS)

The prevalence of sickle cell trait varies throughout the world; in the United States the incidence is 7–10% of African-Americans. The incidence of Hb S in most individuals with hemoglobin AS on electrophoresis is 35–45%; this is influenced by a-thalassemia, which is common in this population. Individuals with a-thalassemia have a two-gene deletion resulting in an Hb S of 25–30%. The life span of people with this trait is normal, and serious complications are very rare. The complete blood cell count is within the normal range (see Fig. 454–2*B*). Hemoglobin electrophoresis is diagnostic.

Complications of sickle cell trait include sudden death during rigorous exercise, splenic infarcts at high altitude, hematuria, hyposthenuria, bacteriuria, and intraocular bleeding leading to blindness. A rare cancer, renal medullary carcinoma, is also associated with sickle cell trait. Most of these complications have been not adequately studied, making counseling difficult. In general, children with sickle cell trait should not have any restrictions on activities. The most importance risk is to future progeny, and the pediatrician should offer counseling to at-risk individuals and families.

454.3 Other Hemoglobinopathies

Hemoglobin C.

The mutation for Hb C is at the same site as Hb S, with lysine instead of valine substituted for glutamine. In the United States, Hb AC occurs in 1:50 and Hb CC occurs in 1:5,000 African-Americans. Hb AC is asymptomatic. Hb CC may result in a mild anemia, splenomegaly, and cholelithiasis; rare cases of spontaneous splenic rupture have been reported. Sickling does not occur. This condition is usually diagnosed through newborn screening programs. Hb C crystallizes, disrupting the red cell membrane (see Fig. 454–2*C*).

Hemoglobin E.

(a_2 $ß_2$ $^{26Glu\text{-}Lys}$). This is the second most common globin mutation worldwide. The hemoglobin mutation activates a cryptic splice site, and the mRNA is less efficiently processed. There are two other hemoglobins with a similar RNA processing defect: hemoglobins Knossos and Malay; these are sometimes called thalassemic hemoglobinopathies, owing to the ineffective erythropoiesis that results from the hemoglobin mutation. Heterozygotes are asymptomatic and homozygotes have a mild microcytic anemia. The phenotype is altered with co-inheritance of a-thalassemia.

Hemoglobin D.

There are 16 variants of Hb D; only one, D-Punjab (Los Angeles), in combination with Hb S produces symptoms of sickle cell disease. This rare hemoglobin is seen in 1–3% of Western Indians and in some Europeans with a tie to India. Heterozygous D is clinically silent. Homozygous D produces a mild to moderate anemia with splenomegaly.

454.4 Unstable Hemoglobin Disorders

About 200 rare unstable hemoglobins have been identified; the most common is Hb Köln. Most individuals seem to have de novo mutations rather than inherited hemoglobin disorders. The most studied are those whose mutation causes unstable heme binding that eventually leads to the denaturation of the hemoglobin molecule. The denatured hemoglobin can be visualized during severe hemolysis or after

splenectomy as Heinz bodies. Unlike the Heinz bodies seen after toxic exposure, in unstable hemoglobins Heinz bodies are present in reticulocytes and older red cells (see Fig. 454–2*D*). Heterozygotes are asymptomatic.

Homozygous children can present in early childhood with anemia and splenomegaly or with unexplained hemolytic anemia. Hemolysis is increased with febrile illness and, with some unstable hemoglobins, the ingestion of oxidant medications (similar to glucose-6-phosphate dehydrogenase). If the spleen is functional, the smear may appear almost normal or have only hypochromasia and basophilic stippling. A diagnosis may be made by demonstrating Heinz bodies, hemoglobin instability, or an abnormal electrophoresis (although some unstable hemoglobins have normal mobility).

Treatment is supportive. Transfusion may be required during hemolytic episodes in severe cases. Oxidative drugs should be avoided, and folate supplementation provided. Splenectomy has been performed, but the complications of splenectomy, including bacterial sepsis and the possibility of developing pulmonary hypertension, should be considered before this therapy.

454.5 Abnormal Hemoglobins with Increased Oxygen Affinity

Over 110 high-affinity hemoglobins have been characterized. These mutations affect the state of configuration of hemoglobin during oxygenation and deoxygenation. Hemoglobin changes structure when in the oxygenated versus the deoxygenated state. The deoxygenated state is termed the T (tense) state and is stabilized by 2,3-DPG. When fully oxygenated, hemoglobin assumes the R (relaxed) state. The exact molecular interactions between these two states are not known. The high-affinity hemoglobins contain mutations that either stabilize the R form or destabilize the T form. The interactions between these two forms are complex, and the mechanisms of the mutations are not known. In most cases the hemoglobins can be identified by hemoglobin electrophoresis; about 20% must be characterized under controlled conditions of measurements of the P_{50} , which will be 9–21?mm?Hg (normal: 23–29?mm?Hg). Because of a decrease in the P_{50} most of these hemoglobins cause an erythrocytosis of 17 to 20?g/dL of hemoglobin. Levels of erythropoietin and 2,3-DPG are normal. Patients are usually asymptomatic, and do not need phlebotomy. If phlebotomy is performed, oxygen delivery could be problematic owing to a lowered hemoglobin.

454.6 Abnormal Hemoglobins Causing Cyanosis

These hemoglobin variants are rare. The major group is the M hemoglobins, of which there are seven. Hemoglobin M variants have mutations in either the a or the ß chain, all in the heme pocket of the hemoglobin molecule. Six of the 7 have a tyrosine residue that covalently bonds with the heme iron, stabilizing it in the oxidized form. These unstable hemoglobins lead to a hemolytic anemia, most pronounced in the ß forms. Clinically, these children are cyanotic from birth without other signs or symptoms of disease if the tyrosine is on the a chain (Hb M Boston, M Iwate). Infants with ß-chain mutations become cyanotic later in infancy owing to the fetal hemoglobin switch (Hb M Saskatoon, Hyde Park, Milwaukee). The abnormal hemoglobins are autosomal dominant and diagnosed by hemoglobin electrophoresis using special techniques and HPLC. There is no treatment; children with the ß form should avoid oxidant drugs.

Low affinity hemoglobins have less cyanosis than the M hemoglobins. The amino acid substitutions destabilize the oxyhemoglobin and lead to decreased oxygen saturation. The best characterized are Hb Kansas and Hb Beth Israel.

454.7 Hereditary Methemoglobinemia

The iron in hemoglobin is normally in the ferrous state (Fe^{2+}), which is essential for its oxygen-transporting function. Under physiologic conditions there is a slow, constant loss of electrons to released oxygen and the ferric (Fe^{3+}) form combines with water, producing methemoglobin (MHg). The predominant intracellular mechanism for the reduction of MHg is cytochrome 5b. This mechanism is over a hundredfold more efficient than the production of MHg, and only 1% of hemoglobin is in the ferric state normally.

MHg may be increased in the red cell owing to exposure to toxic substances or to absence of reductive pathways (NADH-cytochrome b5 reductase deficiency). Toxic methemoglobinemia is much more common than hereditary methemoglobinemia. Infants are particularly vulnerable to hemoglobin oxidation because they have 50% the level of cytochrome b5 reductase that adults do, fetal hemoglobin is more susceptible to oxidation than hemoglobin A, and the more alkaline infant gastrointestinal tract may promote the growth of nitrite producing gram-negative bacteria. When MHg levels are greater than 1.5?g/24?hr, cyanosis is visible (15% MHb); a level of 70% MHg is lethal. The level is usually reported as a percent of normal hemoglobin, and the toxic level is lower at a lower hemoglobin level. Methemoglobinemia has been described in infants who ingested foods and water high in nitrates, who were exposed to aniline teething gels or other chemicals, and in some infants with severe gastroenteritis and acidosis. Methemoglobin may color the blood brown.

Hereditary Methemoglobinemia with Deficiency of NADH Cytochrome b5 Reductase.

These rare disorders are classified as four types. In type I (most common) the deficiency of NADH cytochrome b5 activity is deficient only in the red cells. In type II, the enzyme deficiency is present in all tissues and is characterized in infancy by encephalopathy, mental retardation, spasticity, microcephaly, and growth retardation. In type III, the deficiency occurs in leukocytes, platelets, and red cells; and in type IV there is deficiency of only red cell cytochrome b5.

Clinically, cyanosis may vary in intensity with season and diet. The time at onset of cyanosis also varies; in some patients it appears at birth, in others as late as adolescence. Although as much as 50% of the total circulating hemoglobin may be in the form of nonfunctional methemoglobin, little or no cardiorespiratory distress occurs in these patients, except on exertion.

Daily oral *treatment* with ascorbic acid (200–500?mg/day in divided doses) gradually

reduces the methemoglobin to about 10% of the total pigment and alleviates the cyanosis as long as therapy is continued. Chronic high doses of ascorbic acid have been associated with hyperoxaluria and renal stone formation. Ascorbic acid should not be used for treatment of toxic methemoglobinemia. Methylene blue given intravenously (1–2?mg/kg initially) is used to treat toxic methemoglobinemia. An oral dose can be administered (3–5?mg/kg/24?hr) as maintenance therapy. Methylene blue should not be used in patients with glucose-6-dehydrogenase deficiency; it is ineffective and can cause severe oxidant hemolysis.

454.8 Syndromes of Hereditary Persistence of Fetal Hemoglobin (HPFH)

These syndromes are a form of thalassemia; a mutation is associated with a decrease in the production of either or both ß and d globins. There is an imbalance in the a:non-a synthetic ratio (see Chapter 454.9) characteristic of thalassemia. Over 20 variants of HPFH have been described. They are deletional, $dß^0$ (Black, Ghanaian, Italian), nondeletional (Tunisian, Japanese, Australian), linked to the ß-globin-gene cluster (British, Italian-Chinese, Black), or unlinked to the ß-globin-gene cluster (Atlanta, Czech, Seattle). The $dß^0$ forms have deletions of the entire d- and ß-gene sequences, the most common in the United States being the Black (HPFH 1) variant. Because the d and ß genes have been deleted there is production only of ? globin and formation of Hb F. In the homozygous form there are no manifestations of thalassemia. There is only Hb F with very mild anemia and slight microcytosis. When inherited with other variant hemoglobins, Hb F is elevated in the 20–30% range; when inherited with Hb S, there is an amelioration of sickle hemoglobinopathy with some mild manifestations. Avascular necrosis of the hips has been reported in Hb SS disease with HPFH.

454.9 Thalassemia Syndromes

The thalassemias are the most common genetic disorder on a worldwide basis. The selective pressures that have made the thalassemias so common are not known but are assumed to relate to the geographic distribution of malaria. Children with thalassemia have a shorter red cell life, fetal hemoglobin in their red cells until an older age than normal, and red cells that are more sensitive to oxidative stress.

Epidemiology.

Although there are more than 200 mutations for ß-thalassemia, most are rare. About 20 common alleles constitute 80% of the known thalassemias worldwide; 3% of the world's population carry genes for ß-thalassemia, and in Southeast Asia 5–10% of the population carry genes for a-thalassemia. In a particular area there are fewer common alleles.

Pathophysiology.

Mutations in ß-thalassemia involve globin gene deletions, promoter region mutations, termination mutations, splice site mutations, and other rare mutations. There are relatively few a-thalassemia mutations; most are deletions. Selected features of the thalassemias can be seen in Table 454–4 . The key feature is the fact that there is a globin chain imbalance. In the bone marrow the thalassemic mutations disrupt the maturation of the red cell, resulting in ineffective erythropoiesis; the marrow is hyperactive, but there are relatively few reticulocytes and severe anemia. In ß-thalassemias there is an excess of a-globin chains relative to ß- and ?-globin chains; a-globin tetramers (a_4) are formed, and these inclusions interact with the red cell membrane and shorten red cell survival, leading to anemia and increased erythroid production. The ?-globin chains are produced in normal amounts, leading to an elevated Hb F (a_2 $?_2$). The d-globin chains are also produced in normal amounts, leading to an elevated Hb A_2 (a_2 d_2) in ß-thalassemia. In a-thalassemia there are relatively fewer a-globin chains and an excess of ß- and ?-globin chains. These excess chains form Bart's hemoglobin ($?_4$) in fetal life and Hb H ($ß_4$) after birth. These abnormal tetramers are not as lethal but lead to extravascular hemolysis.

Homozygous $ß^0$ - Thalassemia (Thalassemia Major, Cooley's Anemia)

Clinical Manifestations.

These children usually become symptomatic from progressive hemolytic anemia with profound weakness and cardiac decompensation during the second 6 mo of life if not treated. Depending on the mutation and degree of fetal hemoglobin production, transfusions in thalassemia major are necessary in the second month of life or the second year of life but rarely later. The decision to transfuse depends on the child's ability to compensate for the degree of anemia. Most infants and children have cardiac decompensation at hemoglobins of 4?g/dL or less. Generally, fatigue, poor appetite, and lethargy are late findings of severe anemia in an infant or child. These were common before transfusions were standard therapy. The classic presentation of children with severe thalassemic facies, pathologic fractures, marked hepatosplenomegaly, and cachexia is still seen in some developing countries. The spleen may become so enlarged that it causes mechanical discomfort and secondary hypersplenism. These are features of ineffective erythropoiesis (Fig. 454–3): expanded medullary spaces (with massive expansion of the marrow of the face and skull), extramedullary hematopoiesis, and a huge caloric need. The hepatosplenomegaly may interfere with nutritional support. Pallor, hemosiderosis, and jaundice may combine to produce a greenish brown complexion. Because of the anemia there is also an increase in iron absorption, with toxicity leading to further complications, if the child survives long enough to develop them. Many of these features became less severe and infrequent with transfusion therapy, but transfusional hemosiderosis is a consequent complication. Many of the complications of thalassemia seen in developed countries today are the result of iron overload: in the liver, fibrosis and cirrhosis; in the beta cells of the pancreas, diabetes mellitus; in the pituitary, testis, and ovaries, growth retardation and hypogonadotropic hypogonadism; in the parathyroid, hypocalcemia and osteoporosis; and in the heart, arrhythmias, myocarditis, and intractable cardiac failure. Most, if not all, of these complications can be avoided by the consistent use of an iron chelator. However, chelation therapy also has associated complications.

Laboratory Findings.

The infant is born only with Hb F or, in some cases, Hb F and Hb E (heterozygosity for $ß^0$ -thalassemia). Eventually in $ß^0$ -thalassemia there is severe anemia, few

reticulocytes, numerous nucleated red cells, and microcytosis with almost no normal-appearing red cells on the smear (see Fig. 454–2*E*). The hemoglobin level falls progressively to lower than

TABLE 454.9- 4 -- The Thalassemias

Thalassemia	Globin Genotype	Features	Expression	Hemoglobin Electrophoresis

Figure 454.9-3 Ineffective erythropoiesis in untransfused 3-year-old patient with thalassemia major. Massive widening of the diploic spaces of the skull on MRI, radiographic appearance of trabeculae seen on plain radiograph, and obliteration of the maxillary sinuses with hematopoietic tissue as seen on computed tomography.

5?g/dL unless transfusions are given. The unconjugated serum bilirubin level is usually elevated, but other chemistries may be normal at an early stage. Even if untransfused, eventually there is iron accumulation with an elevated serum ferritin and saturation of the transferrin. Bone marrow hyperplasia can be seen on radiographs (see Fig. 454–3).

Treatment.

Before initiating chronic transfusions, the diagnosis of ß^{0} -thalassemia should be confirmed and the parents counseled concerning this life-long therapy. Beginning transfusion and chelation therapy are difficult challenges for parents to face early in their child's life. Before beginning transfusion therapy, a red cell phenotype is obtained; blood products that are leukoreduced and phenotypically matched for the Rh and Kell antigens are required for transfusion. If there is the possibility of a bone marrow transplant, the blood should be negative for cytomegalovirus and irradiated.

Transfusion therapy promotes general health and well-being and avoids the consequences of ineffective erythropoiesis. Iron overload is inevitable, and “hyper”-transfusion should be avoided. A post-transfusion hemoglobin level of 9.5?g/dL is the goal. Banked blood in developed countries is generally safe. Designated donors are not encouraged; some blood centers have “partner” programs, pairing donors and recipients, which decreases the exposure to multiple red cell antigens. As a child grows, more donors will be needed.

Transfusional hemosiderosis causes many of the complications of thalassemia major. Assessment of iron overloading is best achieved by liver biopsy, supplemented by ferritometry and the measurement of serum ferritin. Liver biopsy is the only method that is reproducible and should be available in centers caring for thalassemic patients. There are few available ferritometers. Ferritin can only provide an assessment of the trend of the iron status for a particular patient.

Transfusional hemosiderosis can be prevented by the use of deferoxamine (Desferal). Deferoxamine chelates iron and some other divalent cations, allowing their excretion in the urine and the stool. If used appropriately, a negative iron balance can be achieved. Deferoxamine is given subcutaneously over 10–12?hr, 5–6 days a week. It should be used cautiously in young children. The side effects include ototoxicity with high-frequency hearing

loss, retinal changes, and bone dysplasia with truncal shortening. Oral iron chelators (deferiprone: L-1) have not been as effective as deferoxamine and there is a concern about their causing neutropenia, arthritis, and hepatic fibrosis. Other iron chelators are being studied for oral and subcutaneous use.

Splenectomy may be indicated for patients with thalassemia intermedia who have a falling steady-state hemoglobin and for transfused patients with a rising transfusion requirement. However, splenectomy may have serious infectious consequences. Because of the increased risk of infection after splenectomy, all patients should be fully immunized against encapsulated bacteria before splenectomy, and they subsequently should be on long-term penicillin prophylaxis. Preliminary evidence that splenectomy may lead to pulmonary hypertension has led to anticoagulation being considered for some splenectomized patients.

Bone marrow transplantation has successfully cured over a thousand patients who have thalassemia major. Most success has been in children younger than 15 yr of age without iron overload and hepatomegaly who have HLA-matched siblings. All children who have an HLA-matched sibling should be offered the option of bone marrow transplantation.

Other ß-Thalassemia Syndromes

The ß-thalassemia syndromes are broken into six groups: ß-thalassemias, dß-thalassemias, ?-thalassemias, d-thalassemias, e?dß-thalassemias, and the HPFH syndrome (see Chapter 454.8). Most of these thalassemias are relatively rare, some being found only in family groups. The ß-thalassemias can also be classified clinically as thalassemia trait, minima, minor, intermediate, and major, reflecting the degree of anemia. The genetic classification does not necessarily define the phenotype, and the degree of anemia does not always predict the genetic classification.

Thalassemia intermedia can be any combination of ß-thalassemia mutations ($ß^0$ /$ß^+$, $ß^0$ /$ß^{variant}$, E/$ß^0$), which will lead to a phenotype of microcytic anemia with hemoglobin of about 7?g/dL. There is controversy about whether to transfuse these children. They will certainly develop a degree of medullary hyperplasia, nutritional hemosiderosis perhaps requiring chelation, splenomegaly, and other complications of thalassemia and iron overload. Extramedullary hematopoiesis can occur in the vertebral canal, compressing the spinal cord and causing neurologic symptoms; the latter is a medical emergency requiring immediate local radiation therapy to halt erythropoiesis. Transfusion will alleviate the thalassemic manifestations and hasten the need for chelation. A splenectomy puts the child at risk for infection and pulmonary hypertension.

The thalassemias classified as *minima* and *minor* are usually heterozygotes ($ß^0$ /ß, $ß^+$ /$ß^+$) having a phenotype more severe than trait but not as severe as intermedia. These children should be investigated for their genotype and monitored for iron accumulation. The ß-thalassemias are influenced by the presence of a-thalassemia: a-thalassemia trait leading to less severe anemia and duplicated a genes (aaa/aa(leading to more severe thalassemia. Frequently, individuals who are in these groups require transfusions in adolescence or adulthood; some may be candidates for chemotherapy such as hydroxyurea.

Thalassemia trait is frequently misdiagnosed as iron deficiency in children because the two are similar hematologically and iron deficiency is much more prevalent. A short course of iron and re-evaluation is all that is required to separate those children who will need further evaluation. Children who have ß-thalassemia trait will have a persistent red cell distribution width, and on hemoglobin electrophoresis they will have an elevated Hb F and diagnostically elevated Hb A_2 . There are “silent” forms of thalassemia trait, and if the family history is suggestive, further studies may be indicated.

a-Thalassemia

The same evolutionary pressures that produced the ß-thalassemia and sickle hemoglobinopathies produced a-thalassemia. Infants are identified in the newborn period by the increased production of Bart's hemoglobin ($?_4$) during fetal life and its presence at birth. Although these thalassemias occur in all malarious areas, they are most common in Southeast Asia. Deletion mutations are common in the a-thalassemias and rare in ß-thalassemia. The variety of phenotypes seen in ß-thalassemia are lacking in a-thalassemia. There are four a-globin genes and four deletional a-thalassemia phenotypes. There are five common a^0 -thalassemia mutations, $^{-FIL}$, $^{-MED}$, $^{-THAI}$, $^{-SEA}$, and $^{-(a)20.5}$ deletions, and two a^+ -thalassemia mutations, -$a^{3.7}$ and -$a^{4.2}$. They can be identified by polymerase chain reaction analysis. Most of these deletions, with the exception of the SEA deletion, common in Southeast Asia, include the ?-globin gene and are not compatible with life in the homozygous state. In addition to these deletional mutations there are also nondeletional a-globin gene mutations, the most common being Constant Spring

(a^{CS} a); these mutations cause a more severe anemia and clinical course than the deletional mutations.

The deletion of one a-globin gene (silent trait) is not identifiable hematologically; individuals with this deletion are usually diagnosed after the birth of a child with a two gene deletion or Hb H ($ß_4$). This deletion is common in African-Americans.

The deletion of two a-globin genes results in a-thalassemia trait. The globin genes can be lost in trans, -a/-a or cist, such as a,a/$^{-SEA}$. The cist or a^0 mutations combined with other mutations can lead to Hb H or a-thalassemia major. The a-thalassemia traits present as a microcytic anemia that can be mistaken for iron-deficiency anemia (see Fig. 454–2*F*). The hemoglobin electrophoresis is normal. The diagnosis of iron deficiency must be eliminated and the diagnosis presumed or confirmed by DNA testing.

The deletion of three a-globin genes leads to the diagnosis of **Hb H disease**. This form of a-thalassemia is significant for a marked microcytosis and anemia; it is identified by hemoglobin electrophoresis. Although there have been few studies of this hemoglobinopathy, it is generally asymptomatic with a moderate anemia and mild splenomegaly, and, occasionally, scleral icterus or cholelithiasis is present. Although brilliant cresyl blue can stain Hb H, it is rarely used for diagnosis. Transfusion is not usually necessary for treatment of the anemia.

The deletion of all four a-globin genes causes profound anemia during fetal life, resulting in hydrops fetalis; the ?-globin gene must be present for fetal survival. There are no normal hemoglobins present at birth (primarily Bart's, with hemoglobins Gower 1, Gower 2, and Portland). If the fetus survives, immediate exchange transfusion is indicated. These infants with *a-thalassemia major* are transfusion dependent. There have been at least two successful bone marrow transplants that cured this disease.

The presence of *a nondeletional a-globin mutation* with a two-gene deletion results in a more severe anemia, increased hepatosplenomegaly, increased jaundice, and a much more severe clinical course than Hb H disease. Hb H Constant Spring is the most common form (-a/a,a^{CS}).

Treatment of the a-thalassemia deletion syndromes consists of folate supplementation, possible splenectomy (with the attendant risks), intermittent transfusion during severe anemia for the nondeletion Hb H diseases, and chronic transfusion therapy or bone marrow transplant for survivors of hydrops fetalis. These children also should not be exposed to oxidant medications.

Iron Overload Disorders

The disorders leading to iron overload are not disorders of hemoglobin. **Hereditary hemochromatosis** (HH) is a disorder of iron absorption leading to toxicity in the fourth to fifth decades of life. Iron absorption is primarily in the liver, heart, and pancreas leading to hepatic cirrhosis and liver failure. It has a prevalence of 1:250 in white Northern Europeans. There are two alleles of the *HFE* gene: 845 G?A (C282Y) and 187 C?G (H63D). These alleles have been associated with hereditary hemtochomatosis. Expression of the C282Y gene is homozygous in 84–100% of individuals with HH (type 1). A second mutation, H63D, is found in combination with C282Y in 2–7% of HH. There are individuals with HH who have neither mutation (type 3). Diagnosis can be made by evaluation of transferrin saturation and ferritin. Treatment is phlebotomy.

There are three pediatric forms of iron overload. Juvenile hemochromatosis (type 2), atransferrinemia/hypotransferrinemia, and neonatal hemochromatosis. **Juvenile hemochromatosis** differs from HH in that the iron loading is primarily in the heart and endocrine system with associated morbidity (i.e., cardiac arrhythmias and failure, diabetes mellitus). Without phlebotomy, death occurs in the third decade. There is no genetic determinant. Infants born with **atransferrinemia** have a disorder similar to HH but also have anemia owing to the lack of transferrin. **Neonatal hemochromatosis** is a rare disease that presents as hepatic iron overload leading to liver dysfunction and failure in the neonatal period. It is sometimes associated with neonatal giant cell hepatitis.

Chapter 455 - Enzymatic Defects

George B. Segel

DEFICIENCIES OF ENZYMES OF THE GLYCOLYTIC PATHWAY

Various red blood cell (RBC) enzymatic defects produce hemolytic anemias, characterized by a lack of spherocytes and few distinguishing features on the blood film. Deficiencies of most of the enzymes in both the anaerobic Embden-Meyerhof pathway and the oxidative hexose monophosphate (pentose) shunt have been described (Fig. 455–1). The most common glycolytic enzyme defect as a cause of hemolytic anemia is pyruvate kinase (PK) deficiency, although it is a rare disorder, with only 300–400 cases reported.

455.1 Pyruvate Kinase (PK) Deficiency

A congenital hemolytic anemia occurs in persons homozygous for an autosomal recessive gene that causes either a marked reduction in RBC PK or production of an abnormal enzyme with decreased activity. Generation of adenosine triphosphate (ATP) within RBCs is impaired, and low levels of ATP, pyruvate, and the oxidized form of nicotinamide-adenine dinucleotide (NAD^+) are found (see Fig. 455–1). The concentration of 2,3-diphosphoglycerate (2,3-DPG) is increased, and this increase is beneficial in facilitating oxygen release from hemoglobin but detrimental in inhibiting hexokinase as well as enzymes of the hexose monophosphate shunt. In addition, an unexplained

Figure 455.1-1 Red cell metabolism. Glycolysis and the hexose monophosphate pathway. The enzyme deficiencies clearly associated with hemolysis are shown in bold type.

decrease occurs in the sum of the adenine (ATP, adenosine diphosphate [ADP], and adenosine monophosphate [AMP]) and pyridine (NAD^+ and NADH) nucleotides, and this further impairs glycolysis. As a consequence of decreased ATP, RBCs cannot maintain the potassium and water content; the cells become rigid, and the RBC life span is considerably reduced.

Etiology.

There are two mammalian PK genes, but only the *PKLR* gene is expressed in red cells. The human *PKLR* gene has been mapped to chromosome 1q21, and 133 mutations are reported in this structural gene, which codes for a protein with 574 amino acids and forms a functional tetramer. Most affected patients are compound heterozygotes for two different PK gene defects. The many possible combinations likely account for the variability in clinical severity.

Clinical Manifestations and Laboratory Findings.

The clinical manifestations vary from a severe neonatal hemolytic anemia to mild, well-compensated hemolysis noted first in adulthood. Severe jaundice and anemia may occur in the neonatal period, and kernicterus has been reported. The hemolysis in older children and adults varies in severity, with hemoglobin values from 8–12?g/dL associated with some pallor, jaundice, and splenomegaly. These patients usually do not require transfusion. A severe form of the disease has a relatively high incidence among the Amish of the midwestern United States.

Polychromatophilia and mild macrocytosis reflect the elevated reticulocyte count. Spherocytes are uncommon, but a few spiculated pyknocytes usually are found. Nonincubated osmotic fragility is normal. Autohemolysis is moderately or markedly increased, but the addition of glucose does not regularly correct the abnormality as it does in hereditary spherocytosis.

Diagnosis relies on demonstration of a marked reduction of PK activity or an increase in the Michaelis-Menten dissociation constant (Km) for its substrate, phosphoenolpyruvate, in the RBCs. Other RBC enzyme activities are normal, or elevated reflecting the reticulocytosis. No abnormalities of hemoglobin are noted. The white cells have normal PK activity and must be rigorously excluded from hemolysates used to measure PK activity. Heterozygous carriers usually have moderately reduced levels of PK activity.

Treatment.

Exchange transfusions may be indicated for hyperbilirubinemia in newborns. Transfusions of packed RBCs are necessary for severe anemia or for aplastic crises. If the anemia is consistently severe or if frequent transfusions are required, splenectomy should be performed after 5–6 yr of age. Although not curative, the operation may be followed by higher hemoglobin levels and by strikingly high (30–60%) reticulocyte counts. Deaths resulting from overwhelming pneumococcal sepsis have followed splenectomy; thus, immunization with vaccines for encapsulated organisms should be given before splenectomy and prophylactic penicillin should be administered after splenectomy.

455.2 Other Glycolytic Enzyme Deficiencies

Chronic nonspherocytic hemolytic anemias of varying severity have been associated with deficiencies of other enzymes in the glycolytic pathway, including hexokinase, glucose phosphate isomerase, and aldolase, which are inherited as autosomal recessive disorders. *Phosphofructokinase (PFK) deficiency* occurs primarily in Ashkenazi Jews in the United States and results in hemolysis associated with a myopathy classified as glycogen storage disease type VII (see Chapter 76.1). Clinically, a hemolytic anemia is complicated by muscle weakness, exercise intolerance, cramps, and possibly myoglobinuria. Enzyme assays for PFK are low in RBCs and muscle.

Triose phosphate isomerase (TPI) deficiency is an autosomal recessive disorder affecting many systems. Affected patients have hemolytic anemia, cardiac abnormalities, and lower motor neuron and pyramidal tract impairment without mental retardation. They usually die in early childhood. The *TPI* gene has been cloned and sequenced and is localized on chromosome 12.

Phosphoglycerate kinase (PGK) is the first ATP-generating step in glycolysis. At least 23 kindreds with PGK deficiency have been described. PGK is the only glycolytic enzyme inherited on the X chromosome. Affected males may have progressive extrapyramidal disease, myopathy, seizures, and variable mental retardation in conjunction with hemolytic anemia. In a report from Tokyo, nine patients manifested neural/myopathic symptoms with hemolysis; six had hemolysis alone, seven had neural/myopathic symptoms alone, and one person had no symptoms. The gene for PGK is particularly large, spanning 23 kb, and various genetic abnormalities including nucleotide substitutions, gene deletions, missense and splicing mutations result in PGK deficiency.

DEFICIENCIES OF ENZYMES OF THE HEXOSE MONOPHOSPHATE PATHWAY

The most important function of the hexose monophosphate pathway is to maintain glutathione in its reduced state (GSH) as protection against oxidation of RBCs (see Fig. 455–1). About 10% of the glucose taken up by RBCs passes through this pathway to provide the NADPH necessary for conversion of oxidized glutathione (GSSG) to GSH. Maintenance of GSH is essential for the physiologic inactivation of oxidant compounds, such as hydrogen peroxide, that accumulate within RBCs. If glutathione, or any compound or enzyme necessary for maintaining it in the reduced state, is decreased, the SH groups of the RBC membrane are oxidized and the hemoglobin becomes denatured and may precipitate into RBC inclusions called *Heinz bodies*. Once Heinz bodies have formed, an acute hemolytic process results from damage to the RBC membrane by the precipitated hemoglobin, the oxidant agent, and the action of the spleen. The damaged RBCs then are rapidly removed from the circulation.

455.3 Glucose-6-Phosphate Dehydrogenase (G6PD) and Related Deficiencies

G6PD deficiency is the most important disease of the hexose monophosphate pathway and is responsible for two clinical syndromes, an episodic hemolytic anemia

induced by infections, certain drugs, or, rarely, fava beans and a spontaneous chronic nonspherocytic hemolytic anemia. This X-linked enzyme deficiency affects more than 200 million people worldwide, and it represents an example of "balanced polymorphism" in which there is an evolutionary advantage of resistance to falciparum malaria in heterozygous females that outweighs the small negative effect of affected hemizygous males.

The deficiency is caused by inheritance of any of a large number of abnormal alleles of the gene responsible for the synthesis of the G6PD molecule. The *G6PD* gene has been cloned and sequenced, and at least 90 mutations have been identified. Some of these mutations that cause episodic versus chronic hemolysis are shown in Figure 455–2 . Milder disease is associated with mutations near the amino terminus of the G6PD molecule, and chronic nonspherocytic hemolytic anemia with mutations clustered near the carboxyl terminus. The normal enzyme found in most populations is designated G6PD B^+ . A normal variant designated G6PD A^+ is common in the African-American population. More than 100 distinct enzyme variants of G6PD are associated with a wide spectrum of hemolytic disease.

EPISODIC OR INDUCED HEMOLYTIC ANEMIA

Etiology.

G6PD is a central enzyme in the hexose monophosphate shunt of glucose metabolism and catalyzes the conversion of glucose-6-phosphate (G6P) to 6-phosphogluconic acid (6PG).

Figure 455.3-2 Nucleotide substitutions that cause G6PD deficiency. Solid squares denote mutations that cause hereditary nonspherocytic hemolytic anemia. Open squares indicate the location of mutations that cause enzyme deficiency but hemolytic anemia only under conditions of stress. The putative binding sites for glucose-6-phosphate (G6P) and nicotinamide-adenine dinucleotide phosphate (NADP) are indicated by arrows. Note that the mutations that produce nonspherocytic hemolytic anemia are almost all clustered between nucleotides 1089 and 1361, surrounding the NADP-binding domain. The exception is a mutation at nucleotide 637, which is adjacent to the putative G-6-P binding domain at nucleotide 605. (Modified from Beutler E: Glucose-6-phosphate deficiency. N Engl J Med 1991;324:169.)

NADPH is produced in this process and is necessary to maintain glutathione in the reduced state, that is, GSSG?GSH. Glutathione is present in the red cell in millimolar amounts and acts to neutralize agents that potentially oxidize either hemoglobin or components of the red cell membrane. If reduced glutathione cannot be sustained to remove oxygen radicals generated by oxidant drugs, the hemoglobin precipitates forming Heinz bodies, and the red cell membrane is critically damaged. The precipitation of hemoglobin and damage to the membrane result in premature red cell destruction or hemolysis.

Synthesis of RBC G6PD is determined by a gene on the X chromosome. Diseases involving this enzyme therefore occur more frequently in males than in females. About 13% of male African-Americans have a mutant enzyme (G6PD A^-) that results in a deficiency of RBC G6PD activity to 5–15% or less of normal. Italians, Greeks, and other Mediterranean, Middle Eastern, African, and Asian ethnic groups also have a high incidence, ranging from 5–40%, of a variant designated G6PD B^- (G6PD Mediterranean). In these variants, the G6PD activity of homozygous females or hemizygous males is less than 5% of normal. Heterozygous females have an intermediate enzymatic activity and, as an example of random X chromosome inactivation (Lyon hypothesis), have two populations of RBCs: One is normal, and the other is deficient in G6PD activity. Most heterozygous females do not have clinical hemolysis after exposure to oxidant drugs. Rarely, the majority of the RBCs are G6PD deficient in heterozygous females because of random inactivation of the normal X chromosome.

Considerable variation in the defect among various racial groups is noted. For example, the defect in Americans of African descent is less severe than in affected Americans of European descent. In Americans of African descent, the electrophoretically distinct enzyme variant is unstable in vivo, and its activity is decreased primarily in the older RBCs in the circulation. The enzyme activity of RBCs containing the variant enzyme (G6PD B^-) in Americans of European descent is very low, often less than 1% of normal in the entire RBC population. A third common mutant enzyme with markedly reduced activity (G6PD Canton) occurs in about 5% of the Chinese population. A large number of other rare enzyme variants have been associated with drug-induced hemolysis.

Clinical Manifestations.

In the usual pattern of G6PD deficiency, symptoms develop 24–48?hr after a patient has ingested a substance that has oxidant properties. Drugs that have these properties include aspirin, sulfonamides, and antimalarials such as primaquine (Box 455–1). In some patients, ingestion of fava beans, a Mediterranean dietary staple, may also produce an acute and severe hemolytic syndrome called *favism*. This results from oxidative products derived from two glucosidic compounds, vicine and convicine, which are hydrolyzed to divicine and isouramil, ultimately producing hydrogen peroxide and other reactive oxygen products.

The degree of hemolysis varies with the inciting agent, the amount ingested, and the severity of the enzyme deficiency in the patient. In severe cases, hemoglobinuria and jaundice result, and the hemoglobin concentration may fall precipitously and be life threatening. In the A^- variety (Americans of African descent), the stability of the folded protein dimer is impaired, and this defect is accentuated as RBCs age. Thus, some spontaneous recovery of the hemolysis may be observed even if administration of the drug is continued. This recovery is a result of the age-labile enzyme, which is abundant and more stable in younger RBCs. The associated reticulocytosis produces a compensated hemolytic process. Infection also may result in hemolysis, and significant but insidious hemolysis may occur in patients hospitalized for other illnesses even when no exposure to drugs can be documented. In A^- G6PD deficiency, spontaneous hemolysis

may occur in premature but not term infants. In Greek and Chinese newborns with the G6PD B^- and Canton varieties, the deficiency of G6PD is an important cause of hyperbilirubinemia and potential kernicterus. In a group of Sephardic Jewish female newborn heterozygotes, there was heightened hyperbilirubinemia particularly if the variant promoter (UGT1A1) seen in Gilbert's syndrome was present. When a pregnant woman ingests oxidant drugs, they may be transmitted to her G6PD-deficient fetus, and hemolytic anemia and jaundice may be apparent at birth.

Laboratory Findings.

The onset of acute hemolysis results in a precipitous fall in hemoglobin and hematocrit. If the episode is severe, the hemoglobin-binding proteins such as haptoglobin are saturated, and free hemoglobin may appear in the plasma and subsequently in the urine (see Fig. 449–2). Unstained or supravital preparations of RBCs reveal Heinz bodies (precipitated hemoglobin), which are not visible on the Wright-stained blood film. Because cells containing these inclusions are rapidly removed from the circulation, they are not seen after the first 3–4 days of illness. The blood film reveals a few fragmented cells and polychromatophilic cells (bluish, large RBCs), representing the reticulocytosis, which often is substantial (5–15%).

Diagnosis.

The diagnosis depends on direct or indirect demonstration of reduced G6PD activity in RBCs. By direct measurement, enzyme activity in affected persons is 10% of normal or less, and the reduction of enzyme is more extreme in Americans of European descent and Asians than in Americans of African descent. Satisfactory screening tests are based on decoloration of methylene blue, on the reduction of methemoglobin, or on the fluorescence of NADPH. Immediately after a hemolytic episode, reticulocytes and young RBCs predominate. These young cells have significantly higher enzyme activity than do older cells in the A^- variety. Testing may therefore have to be deferred for a few weeks before a diagnostically low level of enzyme can be

shown. The diagnosis can be suspected when the G6PD activity is within the low normal range in the presence of a high reticulocyte count. G6PD variants also can be detected by electrophoretic analysis.

Prevention and Treatment.

Prevention of hemolysis constitutes the most important therapeutic measure. When possible, males belonging to ethnic groups with a significant incidence of G6PD deficiency (e.g., Greeks, southern Italians, Sephardic Jews, Filipinos, southern Chinese, Americans of African descent, and Thais) should be tested for the defect before known oxidant drugs are given. The usual doses of aspirin and trimethoprim sulfamethoxazole do not cause clinically relevant hemolysis in the A^- variety. However, aspirin administered in doses used for acute rheumatic fever (60–100?mg/kg/24?hr) may produce a severe hemolytic episode. When hemolysis has occurred, supportive therapy may require blood transfusions, although recovery is the rule when the oxidant agent is removed.

CHRONIC HEMOLYTIC ANEMIAS ASSOCIATED WITH DEFICIENCIES OF G6PD OR RELATED FACTORS

Chronic nonspherocytic hemolytic anemia has been associated with profound deficiency of G6PD caused by enzyme variants, particularly those defective in quantity, activity, or stability. The gene defects leading to chronic hemolysis are located primarily in the region of the NADP binding site near the carboxyl terminus of the protein (see Fig. 455–2). These include the Loma Linda, Tomah, Iowa, Beverly Hills, Nashville, Riverside, Santiago de Cuba, and Andalus variants. Persons with G6PD B^- (Mediterranean) enzyme deficiency occasionally have chronic hemolysis, and the hemolytic process may worsen after ingestion of oxidant drugs. Splenectomy is of little value in these types of chronic hemolysis.

Other enzyme defects may impair the regeneration of GSH as an oxidant “sump” (see Fig. 455–1). A mild, chronic nonspherocytic anemia has been reported in association with decreased RBC GSH, resulting from ?-glutamylcysteine synthetase or glutathione synthetase deficiencies. 6-Phosphogluconate dehydrogenase deficiency has been associated primarily with drug-induced hemolysis, and hemolysis with hyperbilirubinemia has been related to a deficiency of glutathione peroxidase in newborn infants.

Chapter 456 - Hemolytic Anemias Resulting from Extracellular Factors

George B. Segel

AUTOIMMUNE HEMOLYTIC ANEMIAS

A number of extrinsic agents and disorders may lead to premature destruction of red blood cells (RBCs) (see Table 449–1). Among the most clearly defined are antibodies associated with immune hemolytic anemias. The hallmark of this group of diseases is a positive direct antiglobulin (Coombs) test, which detects a coating of immunoglobulin or components of complement on the RBC surface. The most important immune hemolytic disorder in pediatric practice is hemolytic disease of the newborn (erythroblastosis fetalis), caused by transplacental transfer of maternal antibody active against the RBCs of the fetus, that is, isoimmune hemolytic anemia (see Chapter 92.2). Various other immune hemolytic anemias are autoimmune (Box 456–1) and may be idiopathic or related to various infections (Epstein-Barr virus, rarely HIV, cytomegalovirus, and *Mycoplasma*), immunologic diseases (systemic lupus erythematosus [SLE], rheumatoid arthritis), immunodeficiency diseases (agammaglobulinemia and dysgammaglobulinemias), neoplasms (lymphoma, leukemia, and Hodgkin's disease), or drugs (methyldopa, levodopa). Other drugs (penicillins, cephalosporins) cause immune hemolysis that is not autoimmune. The antibodies are “drug dependent” and usually (although not always) have no “specificity” for RBC membrane antigens.

AUTOIMMUNE HEMOLYTIC ANEMIAS ASSOCIATED WITH “WARM” ANTIBODIES

Etiology.

In the autoimmune hemolytic anemias, abnormal antibodies are directed against RBCs but the pathogenetic mechanisms are uncertain. The autoantibody may be produced as an inappropriate immune response to an RBC antigen or to another antigenic epitope similar to an RBC antigen. Alternatively, an infectious agent may in some way alter the RBC membrane so that it becomes “foreign” or antigenic to the host. The antibodies usually react to epitopes (antigens) that are “public” or common to all human RBC such as Rh proteins.

In most instances of warm antibody hemolysis, no underlying cause can be found, and it is called *primary* or *idiopathic* (see Box 456–1). If the autoimmune hemolysis is associated with an underlying disease such as a lymphoproliferative disorder, SLE, or immunodeficiency, it is called *secondary*. In as many as 20% of cases of immune hemolysis, drugs may be implicated.

Drugs (e.g., penicillin or sometimes cephalosporins) that cause hemolysis via the “hapten” mechanism (immune but not autoimmune) bind tightly to the RBC membrane (see Box 456–1). Antibodies to the drug, either newly or previously formed, bind to the drug molecules on RBCs, mediating their destruction in the spleen. In other cases, certain drugs, such as quinine and quinidine, do not bind to RBCs but rather form part of a “ternary complex,” consisting of the drug, an RBC membrane

  - Viral syndromes (most common)

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

- Hapten/drug adsorption (e.g., penicillin)
- Ternary (immune) complex (e.g., quinine or quinidine)
- True autoantibody induction (e.g., methyldopa)

Modified from Packman CH: Autoimmune hemolytic anemias. In Rakel R (editor): Conn's Current Therapy. Philadelphia, WB Saunders, 1995, p 305.

antigen, and an antibody that recognizes both (see Box 456–1). Methyldopa and sometimes cephalosporins may by unknown mechanisms incite true autoantibodies to RBC membrane antigens, so that the presence of the drug is not required to cause hemolysis.

Clinical Manifestations.

Autoimmune hemolytic anemias may occur in either of two general clinical patterns. The first, an acute transient type lasting 3–6 mo and occurring predominantly in children ages 2–12 yr, accounts for 70–80% of patients. It is frequently preceded by an infection, usually respiratory. The onset may be acute, with prostration, pallor, jaundice, pyrexia, and hemoglobinuria, or may be more gradual in onset, with primarily fatigue and pallor. The spleen is usually enlarged and is the primary site for destruction of IgG-coated RBCs. Underlying systemic disorders are unusual in this group. A consistent response to glucocorticoid therapy, low mortality, and full recovery are characteristic of the acute form. The other clinical pattern involves a prolonged and chronic course, which is more frequent in infants and in children older than 12 yr. Hemolysis may continue for many months or years. Abnormalities involving other blood elements are common, and the response to glucocorticoids is variable and inconsistent. Mortality is about 10%, often attributable to an underlying systemic disease.

Laboratory Findings.

In many cases, the anemia is profound, with hemoglobin levels less than 6?g/dL. Considerable spherocytosis and polychromasia are present. More than 50% of the circulating RBCs may be reticulocytes, and nucleated RBCs usually are present. In some cases, a low reticulocyte count may be present, particularly early in the episode. Leukocytosis is common. The platelet count is usually normal, but immune thrombocytopenic purpura is an occasional concomitant (*Evans syndrome*). The prognosis for patients with Evans syndrome is poor, because many develop chronic disease, including some with SLE.

Results of the direct antiglobulin test are strongly positive, and free antibody can sometimes be demonstrated in the serum (indirect Coombs test). These antibodies are active between 35°C and 40°C (“warm” antibodies) and most often belong to the immunoglobulin G (IgG) class. They do not require complement for activity and usually do not produce agglutination in vitro; they are “incomplete.” Antibodies from the serum and those eluted from the RBCs react with RBCs of many persons, in addition to those of the patient. They often have been regarded as nonspecific panagglutinins, but careful studies have revealed specificity for RBC antigens of the Rh system in 70% (~50% adults) of patients. Complement, particularly C3b, may be detected on the RBCs in conjunction with IgG. The Coombs test result is occasionally negative because of the limited sensitivity of the Coombs reaction. A minimum of 260–500 molecules of IgG per cell is necessary on the RBC membrane to produce a positive reaction. Special tests are required to detect the antibody in cases of “Coombs-negative” autoimmune hemolytic anemia.

Treatment.

Transfusions usually are only of transient benefit but may be required initially because of the severity of the anemia until the effect of other treatment is observed. It may be extremely difficult to find compatible blood; blood in which the RBCs give the least positive in vitro reaction by Coombs technique should be chosen. It is sometimes necessary to give blood that is “incompatible” as judged by cross matching. Failure to transfuse a profoundly anemic infant or child may lead to serious morbidity and even death.

Those patients with mild disease and compensated hemolysis may not require any treatment. If the hemolysis is severe and results in significant anemia or symptoms,

treatment with glucocorticoids is initiated. Glucocorticoids decrease the rate of hemolysis by blocking macrophage function, decreasing the production of the autoantibody, and perhaps by enhancing the elution of antibody from the RBCs. Prednisone or its equivalent is administered in a dose of 2?mg/kg/24?hr. In some patients with severe hemolysis, doses up to 6?mg/kg/24?hr of prednisone may be required to reduce the rate of hemolysis. Treatment should be continued until the rate of hemolysis decreases, and then the dose is gradually reduced. If relapse occurs, resumption of full dosage may be necessary. The disease tends to remit spontaneously within a few weeks or months. The Coombs test result may remain positive, even after hemolysis has subsided. When hemolytic anemia remains severe despite glucocorticoid therapy, or if very large doses are necessary to maintain a reasonable hemoglobin level, intravenous immunoglobulin and danazol may be tried. Splenectomy may be beneficial but is complicated by a heightened risk of infection with encapsulated organisms, particularly in patients younger than 2 yr. Prophylaxis is indicated with appropriate vaccines (pneumococcal, meningococcal, and *Haemophilus influenzae* type b) before splenectomy and with oral penicillin after splenectomy. Immunosuppressive agents including new treatments such as rituximab that target ß-lymphocytes, the source of antibody production, may prove useful in chronic cases refractory to conventional therapy. Various plasmapheresis techniques may be used in refractory cases but generally are not helpful.

Course and Prognosis.

The acute variety of idiopathic autoimmune hemolytic disease in childhood varies in severity but is self-limited, and mortality from untreatable anemia is rare. Approximately 30% of patients develop chronic hemolysis, often associated with an underlying disease, such as SLE, lymphoma, or leukemia. Mortality in the chronic cases depends on the primary disorder.

AUTOIMMUNE HEMOLYTIC ANEMIAS ASSOCIATED WITH “COLD” ANTIBODIES

RBC antibodies that are more active at low temperatures and agglutinate RBCs at temperatures below 37℃ have been called “cold” antibodies. They are primarily of the IgM class and require complement for activity. The range of temperature associated with RBC agglutination is called the *thermal amplitude*. A higher thermal amplitude results in hemolysis with less severe exposure to a cold environment. High antibody titers are associated with high thermal amplitude.

Cold Agglutinin Disease.

Cold antibodies usually have specificity for the oligosaccharide antigens of the I/i system. They may occur in primary or idiopathic cold agglutinin disease, secondary to infections such as those from *Mycoplasma pneumoniae* and Epstein-Barr virus or secondary to lymphoproliferative disorders. After *M. pneumoniae* infection, the anti-I levels may increase considerably, and, occasionally, enormous increases may occur to titers of 1:30,000 or greater. The antibody has specificity for the I antigen and, thus, reacts poorly with human cord red blood cells, which possess the i antigen but exhibit low levels of I. Patients with infectious mononucleosis occasionally develop cold agglutinin disease, and the antibodies in these patients often have anti-i specificity. Spontaneous RBC agglutination is observed in the cold, and RBC aggregates are seen on the blood film. The mean corpuscular volume may be spuriously elevated because of cell agglutination. The severity of the hemolysis is related to the thermal amplitude of the antibody, which itself is partly dependent on the IgM antibody titer.

When very high titers of cold antibodies are present and active near body temperature, severe intravascular hemolysis with hemoglobinemia and hemoglobinuria may occur and be heightened on a patient's exposure to cold. Each IgM molecule has the potential to activate a C1 molecule so that large amounts of complement are found on the RBCs in cold agglutinin disease. These sensitized RBCs may undergo intravascular complement lysis or be destroyed in both the liver and spleen.

Cold agglutinin disease is less common in children than in adults, and it more frequently results in an acute, self-limited episode of hemolysis. Glucocorticoids are much less effective in cold agglutinin disease than in disease with warm antibodies. Patients should avoid exposure to cold and should be treated for any underlying disease. In the infrequent patients with severe hemolytic disease, the treatment includes immunosuppression and plasmapheresis. There are several reports of successful treatment of cold agglutinin disease with the monoclonal antibody rituximab that effectively depletes ß-lymphocytes. Splenectomy is not useful in cold agglutinin disease.

Paroxysmal Cold Hemoglobinuria.

This form of hemolytic anemia is mediated by the Donath-Landsteiner hemolysin, which is an IgG cold-reactive autoantibody with anti-P specificity. This antibody fixes large amounts of complement in the cold, and the RBCs lyse as the temperature is increased. Most reported cases are self-limited and usually are associated with nonspecific viral infections. They are now rarely found in association with congenital or acquired syphilis. This disorder may account for 30% of immune hemolytic episodes among children. Treatment includes transfusions for severe anemia and avoidance of cold ambient temperatures.

Chapter 457 - Hemolytic Anemias Secondary to Other Extracellular Factors (See Table 449–1)

George B. Segel

Fragmentation Hemolysis.

Red blood cell (RBC) destruction occurs in this group of diseases because of mechanical injury as the cells traverse a damaged vascular bed. This may be microvascular when RBCs are sheared by fibrin in the capillaries during intravascular coagulation or when renovascular disease accompanies the hemolytic-uremic syndrome (see Chapter 510) or thrombotic thrombocytopenic purpura. Larger vessels may be involved in the Kasabach-Merritt syndrome (giant hemangioma and thrombocytopenia) or when a replacement heart valve is poorly epithelialized. The blood film shows many "schistocytes" or fragmented cells as well as polychromatophilia, reflecting the reticulocytosis (see Fig. 450–2*F*). Secondary iron deficiency may complicate the intravascular hemolysis because of urinary hemoglobin and hemosiderin iron loss (see Fig. 449–2). Treatment should be directed toward the underlying condition, and the prognosis depends on the effectiveness of this treatment. The benefit from transfusion is transient because the transfused cells are destroyed as quickly as those produced by the patient.

Thermal Injury.

Extensive burns may directly damage the RBCs and result in hemolysis that results in the formation of spherocytes. Blood loss and marrow suppression may contribute to anemia and require blood transfusion. Erythropoietin (EPO) has been used as treatment for diminished RBC production.

Renal Disease.

The anemia of uremia is multifactorial in origin. EPO production may be decreased and the marrow suppressed by toxic metabolites. Furthermore, the RBC life span often is shortened owing to retention of metabolites and organic acidemia. The use of EPO in chronic renal disease has markedly decreased the need for blood transfusion.

Liver Disease.

Change in the ratio of cholesterol to phospholipids in the plasma may result in changes in the composition of the RBC membrane and shortening of the RBC life span. Some patients with liver disease have many target RBCs on the blood film, whereas others have a preponderance of spiculated cells.

Toxins and Venoms.

Bacterial sepsis due to *Haemophilus influenzae*, staphylococci, and streptococci may be complicated by accompanying hemolysis. A particularly severe hemolytic anemia has been observed in clostridial infections and results from a hemolytic clostridial toxin. Large numbers of spherocytes may be seen on the blood film in this condition. Spherocytic hemolysis also may be noted after bites by various snakes, including cobras, vipers, and rattlesnakes, which have phospholipases in their venom. Large numbers of bites by insects such as bees, wasps, and yellow jackets also may cause spherocytic hemolysis by a similar mechanism (see Chapter 708).

Wilson Disease.

An acute and self-limited episode of hemolytic anemia may precede by years the onset of hepatic or neurologic symptoms in Wilson disease. This appears to result from the toxic effects of free copper on the RBC membrane. The blood film often (but not always) shows large numbers of spherocytes, and the Coombs test result is negative. Because early diagnosis of Wilson disease permits prophylactic treatment with penicillamine and prevention of hepatic and neurologic disease, correct assessment of this rare type of hemolysis is most important.

Section 4 - *Polycythemia (Erythrocytosis)*

Bruce M. Camitta

Chapter 458 - Primary Polycythemia (Polycythemia Rubra Vera)

Polycythemia exists when the red blood cell (RBC) count, the hemoglobin level, and the total RBC volume all exceed the upper limits of normal. In postpubertal individuals, a red cell mass greater than 25%, above the mean normal value (based on body surface area), or a hematocrit greater than 60 (males) or 56 (females) indicate an absolute erythrocytosis. True polycythemia is characterized by increases of both the RBC and total blood volumes. A decrease in plasma volume, such as occurs in acute dehydration and burns, may result in a high hemoglobin value. However, these situations are more accurately designated hemoconcentration because the RBC mass is not increased and normalization of the plasma volume restores the hemoglobin to normal levels.

Polycythemia vera, a myeloproliferative disorder, has been reported in only a few children. Its pathogenesis is not known. The erythropoietin receptor is normal, and in vitro cultures of erythroid precursors of affected persons do not require added erythropoietin to stimulate growth. Serum erythropoietin levels are normal or low. Diagnostic criteria are listed in Box 458–1 . Phlebotomy and antiplatelet agents (aspirin) reduce the risks of thrombosis and abnormal bleeding. If these are unsuccessful, antiproliferative treatments (hydroxyurea, anagrelide, interferon-a) may be helpful. The risk of transformation of the disease into myelofibrosis or acute leukemia has diminished with discontinuation of the use of alkylating agents and radioactive phosphorus. Prolonged survival is not unusual.

Box 458-1. Diagnosis of Polycythemia Vera

MAJOR CRITERIA

1. Increased red cell mass (see text)
2. Absent causes of secondary polycythemia
3. Palpable splenomegaly
4. Abnormal bone marrow karyotype (acquired)

MINOR CRITERIA

a. Platelets > 400 × 10^9 /L
b. Neutrophils > 400 × 10^9 /L
c. Splenomegaly by scanning
d. Erythropoietin-independent red cell precursor growth or reduced serum erythropoietin

DIAGNOSIS

1 + 2 and 3 or 4

1 + 2 and 2 minor criteria

Chapter 459 - Secondary Polycythemia

The differential diagnosis of secondary polycythemia is shown in Box 459–1 . Polycythemia may be present in any clinical situation associated with chronic arterial oxygen desaturation. *Cardiovascular defects involving right-to-left shunts* and *pulmonary diseases interfering with proper oxygenation* are the most common causes of hypoxic polycythemia. Clinical findings usually include cyanosis, hyperemia of the sclerae and mucous membranes, and clubbing of the fingers. As the hematocrit rises above 65%, clinical manifestations of hyperviscosity, such as headache and hypertension, may require phlebotomy (see also Chapter 92.3). On the other hand, the increased demand for red blood cell (RBC) production may cause iron deficiency. Iron-deficient RBCs are more rigid, further increasing the risk of intracranial thrombosis in these patients. Because microcytosis may occur only as a late manifestation of iron deficiency in children with hypoxic polycythemia, routine periodic assessment of iron status, with treatment of iron deficiency, should be performed in these children. Living at *high altitudes* also causes hypoxic polycythemia; the hemoglobin level increases about 4% for each rise of 1,000?m in altitude. *Partial obstruction of a renal artery* rarely results in polycythemia.

    Erythropoietin level

    Red blood cell colony formation

More subtle forms of hypoxia may also cause polycythemia. *Congenital methemoglobinemia* resulting from a deficiency of cytochrome b5 reductase may cause cyanosis and polycythemia (see Chapter 454.7). This condition is transmitted as an autosomal recessive trait. Most affected individuals are asymptomatic. Neurologic abnormalities may be present in patients whose enzyme deficit is not limited to hematopoietic cells. Dominantly transmitted polycythemia is caused by hemoglobins that have increased oxygen affinity. Cyanosis may occur in the presence of as little as 1.5?g/dL of methemoglobin but is uncommon in other hemoglobin variants unless hyperviscosity results in localized hypoxemia (see Chapter 92.3).

Polycythemia has also been associated with benign and malignant *tumors* that secrete erythropoietin. Exogenous or endogenous excess of *anabolic steroids* also may cause polycythemia. Polycythemias have been transmitted as dominant or

recessive conditions. In about 10% of these families, there is an abnormality of the erythropoietin receptor.

Sequential studies to evaluate polycythemia are outlined in Box 459–2 . For mild disease, observation is sufficient. When the hematocrit exceeds 65–70% (hemoglobin > 23?g/dL), blood viscosity markedly increases. Periodic phlebotomies may prevent or decrease symptoms. Apheresed blood should be replaced with plasma or saline to prevent hypovolemia in patients accustomed to a chronically elevated total blood volume.

Section 5 - *The Pancytopenias*

Pancytopenia can result from a failure of production of hematopoietic progenitors, their destruction, or replacement of the bone marrow by tumor or fibrosis. Although selective cytopenias are important clinical entities (see Chapters 121.1 , 440 , 441 , 442 , 443 , 444 , and 476), pancytopenia is a loss of all marrow elements. The clinical consequences include anemia, neutropenia, and thrombocytopenia and, depending on the degree and duration of their impairment, can lead to serious illness and death. Pancytopenia can be constitutional, arising as a consequence of an inherited genetic defect affecting hematopoietic progenitors, or can be acquired as a consequence of either direct destruction of progenitors, immunemediated damage to either hematopoietic progenitors or their nurturing microenvironment, or suppression of or crowding out of progenitors by tumor cells or fibrosis. In this section, the constitutional and acquired pancytopenias are considered separately. Because the principles of supportive care are generally independent of the etiology of the pancytopenia, they are presented in Chapters 462 463 , 464 , 465 , and 466 .

Chapter 460 - The Constitutional Pancytopenias

Alan D. D'Andrea

Etiology.

Although Fanconi anemia is the best-recognized constitutional pancytopenia, a number of other infrequent genetic disorders have also been implicated. These genetic syndromes (Table 460–1) include various modes of inheritance and may be associated with a number of congenital abnormalities, especially of the bones, kidneys, and heart. Because the hematologic manifestations of the congenital pancytopenias may not become manifested until the first years to even decades of life, a genetic predisposition to bone marrow failure should be considered in all cases of aplastic anemia in children (see later). These disorders can be autosomal recessive (e.g., Fanconi anemia, dyskeratosis congenita), X linked, or autosomal dominant (e.g., dyskeratosis congenita). Several of these genetic disorders may present initially with a single cytopenia and subsequently progress to pancytopenia

(e.g., Shwachman-Diamond syndrome, amegakaryocytic thrombocytopenia, reticular dysgenesis). In addition, a number of inheritable familial marrow dysfunction syndromes have been associated with pancytopenia (which can also be autosomal recessive, autosomal dominant, or X linked), and aplastic anemia also occurs in association with other genetic disorders (e.g., Down, Dubowitz, and Seckel syndromes). Thus, pancytopenia can be either the primary disease manifestation or can emerge as a rare complication during the course of another illness. Because of the chromosomal fragility or defective repair mechanisms that may be associated, several of these disorders can also be complicated by cancer or other organ dysfunction(s). In addition, if such patients are treated for a malignancy with radiation or chemotherapy, they may experience excessive toxicity owing to their underlying defect.

Epidemiology.

Although the true incidence of these disorders is unknown, the constitutional pancytopenias are rare. The most common disorder is Fanconi anemia, of which approximately 1,000 cases have been described, in contrast to only about 45 cases of amegakaryocytic thrombocytopenia. Depending on geography, the heterozygote frequency of Fanconi anemia ranges from 1/100 to 1/300. The familial aplastic anemias are much less common.

Pathology and Pathogenesis.

One of the hallmarks of Fanconi anemia is evidence of spontaneous or clastogen-induced

Modified from Alter BP, Young NS: The bone marrow failure syndromes. In Nathan DG, Orkin FA (editors): Nathan and Oski's Hematology of Infancy and Children, 5th ed. Philadelphia, WB Saunders, 1998.

chromosome breaks. Lymphoid, hematopoietic (including progenitors), and fibroblast

cells from patients with Fanconi anemia demonstrate a number of cytogenetic abnormalities, including defective DNA repair, increased susceptibility of hematopoietic cells to oxidant stress, and decreased cell survival. Eight genetic complementation groups of Fanconi anemia have been identified (FA subtypes A, B, C, D1, D2, E, F, and G). Six of the corresponding FA genes have been cloned, and the six encoded FA proteins interact in a common biochemical pathway regulating DNA repair. It is likely that the absence of these gene products contributes directly to the poor growth of hematopoietic progenitor cells and the heightened risk of malignancies. Depressed levels of granulocyte-macrophage colony- stimulating factor (GM-CSF), stem cell factor, and interleukin-6 (IL-6) also have been observed in children with Fanconi syndrome, suggesting that an abnormal cytokine network contributes to the pathogenesis of the bone marrow failure in these patients. Increased cellular sensitivity to interferon-? may account, at least in part, for the pancytopenia of Fanconi anemia.

Chromosome breakage has also been observed in approximately 10% of patients with dyskeratosis congenita, and decreased hematopoietic cytokines have been found in some patients with the Shwachman-Diamond syndrome. However, the pathogenesis of these disorders and that of the familial marrow dysfunction syndromes remains poorly defined. Two of the human disease genes corresponding to dyskeratosis congenita have been cloned.

Clinical Manifestations.

Various physical abnormalities accompany most of the congenital pancytopenias, particularly Fanconi anemia and dyskeratosis congenita. Patients having Fanconi anemia have hyperpigmentation and café-au-lait spots, skeletal abnormalities (especially absent or hypoplastic thumbs), short stature, and a wide array of integumentary and organ abnormalities. *Dyskeratosis congenita* is also very commonly associated with hyperpigmentation as well as nail dystrophy of both the hands and feet, leukoplakia, and a number of ocular abnormalities, including epiphora, blepharitis, and cataracts. The relative frequencies of these abnormalities are compared in Table 460–1 . Fourteen to 25% of patients with the cytogenetic abnormalities of Fanconi anemia lack the major physical stigmas of Fanconi syndrome and have been designated as having the Estren-Damashek subtype. Such patients may present with isolated bone marrow failure or a new malignancy, in the absence of other manifestations of a genetic syndrome. A diversity of cutaneous, skeletal, growth, and organ abnormalities can also be found in 30–40% of the other congenital and familial pancytopenias, although they do not follow any uniform pattern.

Laboratory Findings.

Depending on the specific disorder, thrombocytopenia, leukopenia, lymphopenia, or anemia generally precedes the onset of pancytopenia. Further, hematologic abnormalities may precede or follow elucidation of other physical defects. As noted earlier, chromosomal breaks occur in most patients with Fanconi anemia compared with 10% of those with dyskeratosis congenita. Children with Fanconi anemia and dyskeratosis congenita generally have macrocytosis as well as mild poikilocytosis and anisocytosis, and their red blood cells (RBCs) contain higher levels of i antigen and hemoglobin F than are found in acquired aplasia. The age at onset of hematologic abnormalities ranges from infancy to adolescence. Once peripheral pancytopenia is evident, bone marrow examination generally confirms a hypoplastic or aplastic state comparable to that in acquired aplastic anemias.

Additional laboratory examination should include skeletal radiographs as well as examination of the genitourinary tract and, depending on the diagnosis, more detailed examination of the eyes, gastrointestinal tract, heart, teeth, and gonads (in males).

Diagnosis.

The presence of characteristic skeletal and cutaneous abnormalities coupled with short stature should suggest the

---

diagnosis of congenital pancytopenia even in the absence of hematologic problems. In contrast, when a child presents with evidence of bone marrow failure, a genetic or familial defect should always be considered and evaluated by cytogenetic examination, including chromosomal breakage studies. This is particularly important because approximately 20% of individuals with congenital pancytopenias may occasionally not have any of the physical abnormalities that are considered characteristic of these syndromes (see Table 460–1).

Complications.

The major complications related to the congenital pancytopenias include the consequences of bone marrow failure, a heightened risk for leukemia and other cancers, and organ complications that are specific to the primary defect (e.g., liver problems in Fanconi syndrome, malabsorption in Shwachman-Diamond syndrome). Because Fanconi anemia has eight distinct subtypes (see earlier), knowledge of a patient's specific subtype or specific mutation may allow a more accurate prediction of the clinical course and the need for early therapy. Infection and bleeding represent the major hematologic manifestations leading to life-threatening complications (see Chapter 462). Depending on their degree and duration, the hematologic abnormalities may respond to supportive care initially, but when pancytopenia ensues (depending on the syndrome, this occurs in 20–90% of patients), more aggressive therapies are required. As more knowledge is gained about the molecular and cellular pathogenesis of these syndromes, it may be possible to delay some of the hematologic complications (see Treatment).

Treatment.

The traditional backbone of therapy for patients with congenital anemias has been steroids and androgens (especially oxymetholone or nandrolone), alone or in combination. Although 50–75% of patients show some evidence of improvement with androgens, relapse is common and complications (especially hepatic tumors or obstructive liver disease) occur. Improvements in RBCs generally precede those in white blood cells, and it may take months to achieve a maximum benefit. These therapies have been shown to prolong life by approximately 2 yr and hence can only

be considered palliative.

The only “curative” therapy to date has been bone marrow transplantation. However, patients with congenital pancytopenias also have an increased predisposition to malignancy, and the preparative regimens generally used during bone marrow transplantation can adversely affect this susceptibility. Accordingly, lower doses of alkylating agents in the preparative regimens are appropriate. Furthermore, most patients with Fanconi anemia do not have histocompatible donors. Transplantation from unmatched donors results in considerable morbidity, owing to the increased intensity of graft versus host disease in these children. Encouraging results have been reported when GM-CSF was administered subcutaneously to children with Fanconi anemia and pancytopenia. A significant increase in the neutrophil count was observed in six of seven patients who were treated at the Children's Hospital (Boston), and this was sustained for more than a year without any evidence of leukemia. More transient responses have been observed with granulocyte colony-stimulating factor (G-CSF). Additional follow-up is important, and it is possible that treatment of these patients with multiple cytokines (erythropoietin, IL-3, IL-6) may offer additional benefits. Ultimately, the best hope for these children will emerge from an understanding of the molecular defects that produce the syndromes; once these are identified, gene therapy may become a feasible consideration.

Prognosis.

When marrow failure develops, the prognosis is guarded. Although bone marrow transplantation and hematopoietic growth factor reconstitution offer some hope, neither overcomes the risks for subsequent cancer or other organ complications.

Genetic Counseling.

Once an index case has been identified, genetic counseling is important and must be oriented to the patterns of inheritance and the prospect for prenatal diagnosis. Based on the presence of cytogenetic and chromosomal breakage or, in the case of amegakaryocytic thrombocytopenia, fetal blood platelet counts, a diagnosis can be suspected or confirmed.

Chapter 461 - The Acquired Pancytopenias

Jeffrey D. Hord

Etiology and Epidemiology.

Various drugs, chemicals, toxins, infectious agents, radiation, or immune disorders can result in pancytopenia, by either direct destruction of hematopoietic progenitors, disruption of the marrow microenvironment, or immune-mediated suppression of marrow elements (Box 461–1). Whenever a child presents with pancytopenia, a careful history of exposure to known risk factors should be obtained. The possibility of a genetic predisposition to bone marrow failure should always be considered, even in the absence of the classic associated physical findings (see Chapter 460). A specific cause cannot be identified in most cases of acquired marrow failure in childhood, and these cases are termed “idiopathic.” The overall incidence of acquired aplastic anemia is relatively low, with an approximate incidence in both children and adults, in the United States and Europe, of 2–6 cases per million per year.

Severe bone marrow suppression can develop after exposure to many different drugs and chemicals, including certain chemotherapeutic agents, insecticides, antibiotics, anticonvulsants, nonsteroidal anti-inflammatory agents, antihistamines, sedatives, and metals. Some of the most notable agents are benzene, chloramphenicol, and gold. The severity and duration of the pancytopenia is dependent on the extent of exposure to these agents. A genetic predisposition may exist and may increase the likelihood of pancytopenia after exposure.

A number of viruses can either directly or indirectly result in bone marrow failure. Parvovirus B19 is classically associated with isolated red cell aplasia, but in patients with sickle cell disease or immunodeficiencies it can result in transient pancytopenia (see Chapters 230 and 454). Prolonged pancytopenia can occur after infections with many of the hepatitis viruses, herpesviruses, Epstein-Barr virus (EBV), and cytomegalovirus (CMV). HIV has also been associated with a number of hematologic abnormalities, including anemia, neutropenia, thrombocytopenia, and pancytopenia.

Patients with evidence of bone marrow failure should also be evaluated for paroxysmal nocturnal hemoglobinuria (PNH) and collagen vascular diseases, although these are uncommon causes of pancytopenia in childhood. Pancytopenia without

peripheral blasts may be caused by bone marrow replacement by leukemic blasts or neuroblastoma cells.

Pathology and Pathogenesis.

The hallmark of aplastic anemia is peripheral pancytopenia coupled with hypoplastic or aplastic bone marrow. The severity of the clinical course is related to the degree of myelosuppression. Severe aplastic anemia is defined as a condition in which two or more cell components have become seriously compromised (i.e., an absolute neutrophil count < 500/mm^3 , a platelet count < 20,000/mm^3 , a reticulocyte count < 1% after correction for the hematocrit) in a patient whose bone marrow biopsy material is moderately or severely hypocellular. Bone marrow failure can result from various causes and mechanisms. For example, it may be a consequence of a direct cytotoxic effect on hematopoietic stem cells from a drug or chemical or may result from either cell-mediated or antibody-dependent cytotoxicity. There is evidence that many cases of aplastic anemia are caused by an immune-mediated process with increased circulating activated T lymphocytes producing cytokines (e.g., interferon-?) that suppress hematopoiesis. Abnormalities of the supporting microenvironment or a loss of critical hematopoietic growth factors can contribute to the marrow failure.

Clinical Manifestations, Laboratory Findings, and Differential Diagnosis.

Acquired pancytopenia is usually characterized by anemia, leukopenia, and thrombocytopenia, in the setting of elevated serum cytokine levels. The pancytopenia results in increased risks of fatigue, cardiac failure, infection, and bleeding. Other treatable disorders, such as cancer, collagen vascular disorders, PNH, or infections that may respond to specific therapies (e.g., intravenous immune globulin for parvovirus) should be considered in the differential diagnosis. Careful examination of the peripheral blood smear for RBC, leukocyte, and platelet morphology is important. A reticulocyte count should be performed to assess erythropoietic activity. In children, the possibility of a congenital pancytopenia must always be considered and chromosomal breakage analysis should be performed to evaluate for Fanconi anemia. The presence of fetal hemoglobin suggests a congenital pancytopenia but is not diagnostic. To assess for the possibility of PNH, flow cytometric analysis of erythrocytes for CD48 and CD59 is the most sensitive test. Bone marrow examination should include both aspiration and a biopsy, and the marrow should be carefully evaluated for morphology, cellularity, and cytogenetics.

Complications.

The major complications of severe pancytopenia are predominantly related to the risk of life-threatening bleeding from prolonged thrombocytopenia or to infection secondary to protracted neutropenia. Patients with protracted neutropenia due to bone marrow failure are at risk not only for serious bacterial infections but also for invasive mycoses. The general principles of supportive care that have evolved from the treatment of cancer patients with chemotherapy-related myelosuppression should be fully extended to the care of patients with acquired pancytopenias (see Chapter 164).

Treatment.

The treatment of children with acquired pancytopenia requires comprehensive supportive care coupled with an attempt to treat the underlying marrow failure. For patients with a human leukocyte antigen (HLA)–identical sibling marrow donor, allogeneic bone marrow transplantation offers a 90% chance of long-term survival. The risks associated with this approach include the immediate complications of the transplantation, graft failure, graft versus host disease, and the risk of secondary cancers (see Chapters 125 and 129). The life-threatening problem of graft failure has diminished with the incorporation of antithymocyte globulin (ATG) and cyclophosphamide into the transplant conditioning regimen. Only one of five patients has an HLA-matched sibling donor so allogeneic bone marrow transplant is not an option for the majority of patients.

For those without a sibling donor, the major form of therapy is immunosuppression with ATG and cyclosporine combined with a hematopoietic colony-stimulating factor (e.g., granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor). Response to this combination therapy is in the range of 60–80%, but a few responders will relapse. There is an increased risk of developing clonal bone marrow diseases such as leukemia, myelodysplasia, or PNH after immunosuppression. The risk for developing clonal disease after immunosuppression has been estimated as high as 40%. For those who fail to respond to immunosuppression or relapse after immunosuppression, matched unrelated donor bone marrow transplantation and high-dose cyclophosphamide remain treatment options. Other therapies that have been used in the past with inconsistent results include androgens, corticosteroids, and plasmapheresis. Alternative marrow transplants continue to be studied as a therapeutic intervention in refractory aplastic anemia.

Prognosis.

Spontaneous recovery rarely occurs. Severe pancytopenia left untreated has an overall mortality rate of approximately 50% within 6 mo of diagnosis and more than 75% overall, with infection and hemorrhage the major causes of morbidity and mortality. Fortunately, the majority of children with acquired severe aplastic anemia will respond to allogeneic marrow transplantation or immunosuppression/cytokine, leaving them with normal or near-normal blood cell counts. For those who fail to respond to front-line therapy, prognosis remains poor.

PANCYTOPENIA CAUSED BY MARROW REPLACEMENT

Processes that either infiltrate or replace the bone marrow can present as acquired pancytopenia. This can occur either before or during malignancy (classically, neuroblastoma or leukemia) or as a consequence of myelofibrosis, myelodysplasia, or osteoporosis. Although uncommon, evidence of a hypoplastic anemia can precede, generally by months, the onset of acute leukemia. This is important to appreciate in evaluating and monitoring children who present with what appears to be an acquired aplastic anemia. Morphologic examination of the peripheral blood and the bone marrow as well as marrow cytogenetic studies are critically important in making the diagnoses of leukemia, myelofibrosis, and myelodysplasia.

Myelodysplasia (MDS) in children is very rare but the clinical course is more aggressive than the same category of MDS in adults. About one half of the children with reported cases of MDS have had clonal abnormalities involving chromosome 7 (usually monosomy 7). The transition time from pediatric MDS to acute leukemia is relatively short at 14 to 26 mo, so aggressive treatment such as bone marrow transplantation (BMT) must be considered shortly after diagnosis. With conventional chemotherapy there is a 20–25% long-term survival, but with allogeneic BMT the survival increases to about 50%. One exception may be MDS/acute myelocytic leukemia in children with Down syndrome because this disease in this specific population is very responsive to conventional chemotherapy, with long-term survival rates of greater than 80%.

Section 6 - *Risks of Blood Component Transfusions*

Ronald G. Strauss

Blood component and derivative transfusions frequently are lifesaving. Intensive care of premature neonates and modern therapy for many children with cancer, hematologic disorders, and transplant recipients would be impossible without them. However, transfusions are not without risks and should be given only when true benefits are likely (e.g., to correct a deficiency or dysfunction of a blood element causing a clinically significant problem). The principles of transfusion support for children and adolescents are similar to those for adults, but infants have special needs. Accordingly, each of these two age groups is discussed separately within each section. Many of the transfusion guidelines presented are based on those formulated by the Pediatric Hemotherapy Committee of the American Association of Blood Banks, but they must be adapted to fit local standards of practice. In particular, terms expressed on the tables, such as “severe” and “symptomatic,” must be defined by local physicians.

Chapter 462 - Red Blood Cell Transfusions and Erythropoietin Therapy

Red blood cells (RBCs) are transfused to increase the oxygen-carrying capacity of the blood and, in turn, to maintain satisfactory tissue oxygenation. Guidelines for RBC transfusions in children and adolescents are similar to those for adults (Box 462–1). However, transfusions may be given more stringently to children because normal hemoglobin levels are lower in healthy children than in adults and, except in defined circumstances, children do not have the underlying cardiorespiratory and vascular diseases that develop with aging in adults. Thus, children should be better able to compensate for RBC loss. In the perioperative period, for example, it is unnecessary for most children to maintain hemoglobin levels of 80?g/L or greater, a level frequently desired for adults. There should be a compelling reason for any postoperative RBC transfusion because most children (without continued bleeding) can quickly restore their RBC mass with iron therapy. As is true for adults, the most important measures in the treatments of acute hemorrhage are, first, to control the hemorrhage and to restore tissue with crystalloid and/or colloid solutions. Then, if the estimated blood loss is greater than 25% of the circulating blood volume (i.e., >17?mL/kg) and the patient's condition remains unstable, RBC transfusions may be indicated. In acutely ill children with severe pulmonary disease requiring assisted ventilation, it is common practice to maintain the hemoglobin level close to the normal range. Although this recommendation seems logical, its efficacy has not been documented by controlled scientific studies.

With chronic anemias, the decision to transfuse RBCs should not be based solely on blood hemoglobin levels because children compensate well and may be asymptomatic despite very low hemoglobin levels. Patients with iron-deficiency anemia, for example, often are treated successfully with oral iron alone, even at hemoglobin levels below 50?g/L. Factors other than hemoglobin concentration to be considered in the decision to transfuse RBCs include (1) the patient's symptoms, signs, and functional capacities; (2) the presence of cardiorespiratory, vascular, and central nervous system disease; (3) the cause and anticipated course of the anemia; and (4) alternative therapies such as recombinant human erythropoietin (EPO) therapy, which is known to reduce RBC transfusions and to improve the overall condition of children with chronic renal insufficiency (see Chapter 527.2). In anemias likely to be permanent, one must also balance the detrimental effects of anemia on growth and development versus the potential toxicity of repeated transfusions. RBC transfusions for disorders such as sickle cell anemia and thalassemia are discussed in Chapters 454.1 and 454.9 .

For *neonates*, clearly established indications for RBC transfusions, based on controlled scientific studies, do not exist. Generally, RBCs are given to maintain a hemoglobin value believed to be most desirable for each neonate's clinical status (see Box 462–1). This clinical approach is imprecise, but more physiologic indications, such as RBC mass, available oxygen, and measurements of oxygen delivery and tissue extraction are too cumbersome for clinical practice. Because definitive data are limited, it is important that the pediatricians critically evaluate the need for neonatal RBC transfusions in light of the pathophysiology involved.

Box 462-1. Guidelines for Pediatric RBC Transfusions

CHILDREN AND ADOLESCENTS

Acute loss > 25% circulating blood volume

Hemoglobin < 8.0?g/dL* in perioperative period

Hemoglobin < 13.0?g/dL and *severe* cardiopulmonary disease

Hemoglobin < 8.0?g/dL and *symptomatic* chronic anemia

Hemoglobin < 8.0?g/dL and *marrow failure*

INFANTS WITHIN FIRST 4 MO OF LIFE

Hemoglobin < 13.0?g/dL and *severe* pulmonary disease

Hemoglobin < 10.0?g/dL and *moderate* pulmonary disease

Hemoglobin < 13.0?g/dL and *severe* cardiac disease

Hemoglobin < 10.0?g/dL and major surgery

Hemoglobin < 8.0?g/dL and *symptomatic* anemia

Words in *italics* must be defined for local transfusion guidelines.

*Hematocrit estimated by Hb g/dL × 3.

During the first weeks of life, all neonates experience a decline in circulating RBC mass caused both by physiologic factors and, in sick premature infants, by phlebotomy blood losses. In healthy term infants, the nadir hemoglobin value rarely falls below 9?g/dL at an age of 10–12 wk. This “physiologic” drop in RBCs does not require transfusions. In contrast, the decline occurs earlier and is more pronounced in premature infants, even in those without complicating illnesses, in whom the mean hemoglobin concentration falls to approximately 8?g/dL in infants of 1.0–1.5?kg birthweight and to 7?g/dL in infants weighing less than 1.0?kg. Most infants with birthweight of less than 1.0?kg need RBC transfusions. A key reason the nadir hemoglobin values of premature infants are lower than those of term infants is the former group's relatively diminished EPO output in response to anemia (see Chapters 92.1 and 438). The mechanisms responsible for low plasma EPO levels are only partially defined. One factor is reliance of preterm infants on the liver as the primary site of EPO production during the first weeks of life. This is important because the liver is less responsive than kidneys to anemia and tissue hypoxia. Thus, preterm infants exhibit a sluggish EPO response to falling hematocrit values. Low plasma EPO levels provide a rationale to use recombinant EPO in the treatment of the anemia of prematurity. Unquestionably, proper doses of EPO and iron effectively stimulate neonatal erythropoiesis. However, the efficacy of EPO therapy to substantially diminish the need for RBC transfusions has not been convincingly demonstrated—particularly, for sick, extremely premature neonates—and recombinant EPO has not been widely accepted as treatment for the anemia of prematurity (see Chapter 92.1).

Despite the promise of EPO therapy, many low-birthweight preterm infants need RBC transfusions (see Box 462–1). In neonatal patients with severe respiratory disease, defined as those requiring relatively large quantities of oxygen and ventilator support, it is customary to maintain the blood hemoglobin above 130?g/L (hematocrit > 40%). Proponents believe that transfused RBCs containing adult hemoglobin, with their superior interaction with 2,3-diphosphoglycerate (2,3-DPG), leading to better oxygen offloading than that of fetal hemoglobin, are likely to provide optimal oxygen delivery throughout the period of diminished pulmonary function. Although this practice is widely recommended, little evidence is available to establish its efficacy or to define its optimal use (i.e., the best hemoglobin level for each degree of pulmonary dysfunction). It seems logical to presume that infants with less severe cardiopulmonary disease require less vigorous support, hence, the lower hemoglobin level suggested for those with only moderate disease. Consistent with the rationale for oxygen delivery in neonates with severe respiratory disease, it seems logical to maintain the hemoglobin value above 130?g/L (hematocrit > 40%) in neonates with severe cardiac disease leading to either cyanosis or congestive heart failure.

The optimal hemoglobin level for neonates facing *major surgery* has not been established by definitive studies. However, it seems reasonable to maintain the hemoglobin above 100?g/dL (hematocrit > 30%) because of limited ability of a neonate's heart, lungs, and vasculature to compensate for anemia; the inferior offloading of oxygen because of the diminished interaction between fetal hemoglobin and 2,3-DPG; and the developmental impairment of neonatal renal, hepatic, and neurologic function. This transfusion guideline must be applied with flexibility to individual infants facing different kinds of surgery.

Stable neonates do not require RBC transfusion unless they exhibit clinical problems attributable to anemia. Proponents of RBC transfusions for symptomatic anemia

believe that the low RBC mass contributes to tachypnea, dyspnea, apnea, tachycardia, bradycardia, feeding difficulties, and lethargy and that these problems can be alleviated by transfusing RBCs. However, it is important to remember that the anemia is only one of several possible causes of these problems, and RBC transfusions should only be given when clinical problems seem to be manifestations of anemia (i.e., not otherwise explained).

The RBC product of choice for children and adolescents is the standard suspension of RBCs separated from whole blood by centrifugation and resuspended in an anticoagulant/preservative storage solution at a hematocrit value of about 60%. The usual dose is 10–15?mL/kg, but transfusion volumes vary greatly depending on clinical circumstances (e.g., continued vs. arrested bleeding, hemolysis). For neonates, many centers transfuse the same RBC product as selected for older children, whereas others prefer a packed RBC concentrate (hematocrit of 70–90%). Either is infused slowly (2–4?hr) at a dose of about 15?mL/kg. Because of the small quantity of extracellular fluid given at these relatively high hematocrit values and the slow rate of transfusion, the type of RBC anticoagulant/preservative solution used does not pose risks for premature infants. Packing RBCs by centrifugation at the time the aliquot is issued for transfusion ensures a consistent RBC dose is infused with each transfusion.

The traditional use of relatively fresh RBCs (< 7 days of storage) has been halted in many centers in favor of diminishing donor exposure by using a single unit of RBCs to obtain aliquots for transfusing each infant, regardless of the duration of RBC storage. Neonatologists who insist on transfusing only fresh RBCs generally are fearful of the rise in plasma potassium (K^+) level that occurs in RBC units during extended storage. After 42 days of storage, plasma K^+ levels are 50?mEq/L (0.05?mEq/mL), a value that at first glance seems alarmingly high. However, the actual dose of K^+ transfused in the extracellular fluid is tiny. An infant weighing 1.0?kg, given a 15?mL/kg transfusion of packed RBCs (hematocrit 80%), will receive 3?mL of extracellular fluid that contains only 0.15?mEq of K^+ , and it will be transfused slowly. However, the safety of stored RBCs may not apply to large-volume (>25?mL/kg) transfusions infused rapidly, in which greater doses of K^+ may be harmful.

Chapter 463 - Platelet Transfusions

Guidelines for platelet (PLT) support of *children and adolescents* with quantitative and qualitative PLT disorders are similar to those for adults (Box 463–1), in which the risk of life-threatening bleeding after injury or occurring spontaneously can be related to the severity of thrombocytopenia. PLT transfusions should be given to patients with PLT counts less than 50×10^9 /L when they

are bleeding or are scheduled for an invasive procedure. Studies of patients with thrombocytopenia resulting from bone marrow failure indicate that spontaneous bleeding increases markedly when PLT levels fall below 20×10^9 /L, if serious complications (e.g., infection, organ failure, clotting abnormalities, or anemia) are present. In this setting, prophylactic PLT transfusions are given to maintain a PLT count above 20×10^9 /L. This threshold has been challenged by several studies of adult patients, and a lower PLT transfusion trigger of $5–10 \times 10^9$ /L is recommended for stable patients. However, in practice, severe thrombocytopenia commonly occurs in association with the complications of fever, antimicrobial therapy, active bleeding, need for an invasive procedure, disseminated intravascular coagulation, and other severe clotting abnormalities—situations in which PLT transfusions are given to maintain relatively high PLT counts.

Qualitative PLT disorders may be inherited or acquired (e.g., in advanced hepatic or renal insufficiency or after cardiopulmonary bypass). In such patients, PLT transfusions are justified only if significant bleeding occurs. Because inherited PLT dysfunction is long term and repeated transfusions may lead to alloimmunization and refractoriness, prophylactic PLT transfusions are rarely justified, unless an invasive procedure is planned. In these cases, a bleeding time of greater than twice the upper limit of laboratory normal may be taken as diagnostic evidence that PLT dysfunction exists, but the bleeding time is poorly predictive of hemorrhagic risk or the need to transfuse PLTs. Alternative therapies, particularly desmopressin acetate, should be considered to avoid PLT transfusions.

In *neonates*, hemostasis is quantitatively and qualitatively different from that of older children, and the potential exists for either serious hemorrhage or thrombosis. About 25% of neonates treated in intensive care units exhibit blood PLT counts less than 150×10^9 /L at some time during admission. Multiple pathogenetic mechanisms are involved in these sick neonates, the predominant ones being accelerated PLT destruction plus diminished PLT production, as evidenced by decreased numbers of

megakaryocyte progenitors and relatively low levels of thrombopoietin in thrombocytopenic neonates, when compared with thrombocytopenic children and adults.

Blood PLT counts less than 100×10^9 /L pose significant clinical risks for premature neonates. In one study, infants with birthweight less than 1.5?kg and a blood PLT count less than 100×10^9 /L were compared with nonthrombocytopenic infants of similar birthweight. The bleeding time was prolonged at PLT counts less than 100×10^9 /L, PLT dysfunction was suggested by bleeding times that were disproportionately long for the degree of thrombocytopenia, and hemorrhage was greater in thrombocytopenic infants. Of particular importance, the incidence of intracranial hemorrhage in thrombocytopenic infants with birthweights less than 1.5?kg was 78% versus 48% for nonthrombocytopenic infants of similar size. Moreover, the extent of hemorrhage and neurologic morbidity was greater in the thrombocytopenic group. However, in a randomized trial, transfusing PLTs prophylactically whenever the PLT count fell below 150×10^9 /L to maintain the average PLT count above 200×10^9 /L versus transfusing PLTs only when the PLT count fell below 50×10^9 /L to maintain the average PLT count at about 100×10^9 /L did not diminish the incidence of intracranial hemorrhage (28% vs 26%). Thus, there is no documented benefit to transfusing PLTs for mild thrombocytopenia (i.e., PLT counts < 150 but > 100×10^9 /L). Although basic questions about the relative risks of different degrees of thrombocytopenia in various clinical settings are only partially answered, guidelines acceptable to many neonatologists are listed in Box 463–1 .

The ideal goal of most PLT transfusions is to raise the PLT count to greater than 50 $\times 10^9$ /L, and that for neonates to greater than 100×10^9 /L. This can be achieved consistently in children weighing up to 30?kg by infusing 10?mL/kg of standard (unmodified) PLT concentrates, obtained either from whole

Box 463-1. Guidelines for Pediatric Platelet Transfusions

CHILDREN AND ADOLESCENTS

- PLTs < 50×10^9 /L and bleeding
- PLTs < 50×10^9 /L and *invasive* procedure
- PLTs < 20×10^9 /L and *marrow failure* with hemorrhagic risk factors
- PLTs < 10×10^9 /L and *marrow failure* without hemorrhagic risk factors
- PLTs at any count, but with PLT dysfunction plus bleeding or invasive procedure

INFANTS WITHIN FIRST 4 MO OF LIFE

- PLTs < 100×10^9 /L and bleeding
- PLTs < 50×10^9 /L and *invasive* procedure
- PLTs < 20×10^9 /L and *clinical* stable
- PLTs < 100×10^9 /L and *clinically* unstable
- PLTs at any count, but with PLT dysfunction plus bleeding or invasive procedure

PLTs = platelets.

Words in *italics* must be defined for local transfusion guidelines.

blood units or by plateletpheresis. For larger children, the appropriate dose is four to six pooled whole blood–derived PLT units or one apheresis unit. PLT concentrates

should be transfused as rapidly as the patient's overall condition permits, certainly within 2?hr. Patients requiring repeated PLT transfusions should receive leukocyte-reduced blood products, including PLT concentrates, to diminish alloimmunization and PLT refractoriness and to reduce the risk of transfusion-transmitted cytomegalovirus infections.

Routinely reducing the volume of platelet concentrates for infants and small children by additional centrifugation steps is both unnecessary and unwise. Transfusion of 10?mL/kg of an unmodified PLT concentrate is adequate because it adds 10×10^9 PLTs to 70?mL of blood (the blood volume of a 1-kg neonate), a number calculated to increase the PLT count by 100×10^9 /L. This calculated increment is consistent with the actual increment reported in clinical studies. Moreover, 10?mL/kg is not an excessive transfusion volume, providing the intake of other intravenous fluids, medications, and nutrients is monitored and adjusted. It is important to minimize repeated transfusion of group O PLTs to group A or B recipients because passive anti-A or anti-B in group O plasma can lead to hemolysis. Although proven methods exist to reduce the volume of PLT concentrates when truly warranted (i.e., many transfusions anticipated, in which the quantity of passive anti-A or anti-B might lead to hemolysis, or failure of 10?mL/kg of unmodified PLT concentrate to increase the PLT count), additional processing should be performed with great care because of probable PLT loss, clumping, and dysfunction caused by the additional handling—all of which could diminish the efficacy and increase the toxicity of PLT transfusions.

Chapter 464 - Neutrophil (Granulocyte) Transfusions

Guidelines for granulocyte transfusions (GTX) are listed in Box 464–1 . Although GTX have been used sparingly in the past, the ability to collect markedly higher numbers of neutrophils from donors stimulated with recombinant granulocyte colony-stimulating factor (G-CSF) has led to renewed interest, particularly for marrow or peripheral blood progenitor cell transplantation. GTX should be reconsidered at institutions

---

where neutropenic patients continue to die of progressive bacterial and fungal infections despite the optimal use of antimicrobial agents and recombinant myeloid growth factors.

The role of GTX added to antibiotics for patients with severe neutropenia ($<0.5 \times 10^9$ /L) due to bone marrow failure is similar for both adults and children. Infected neutropenic patients usually respond to antibiotics alone, provided bone marrow function recovers early during the infection. Because children with newly diagnosed leukemia respond rapidly to induction chemotherapy, only rarely are they candidates for GTX. In contrast, infected children with sustained bone marrow failure (i.e., malignant neoplasms resistant to treatment, aplastic anemia, and hematopoietic progenitor cell transplant recipients) may benefit when GTX are added to antibiotics. The use of GTX for bacterial sepsis unresponsive to antibiotics in patients with severe neutropenia ($<0.5 \times 10^9$ /L) is supported by most of the controlled studies (see Chapter 164).

Children with qualitative neutrophil defects (neutrophil dysfunction) usually have adequate numbers of blood neutrophils but are susceptible to serious infections because their cells kill pathogenic microorganisms inefficiently. Neutrophil dysfunction syndromes are rare, and no definitive studies have established the efficacy of GTX. However, several patients with progressive life-threatening infections have improved strikingly with the addition of GTX to antimicrobial therapy. These disorders are chronic, and because of the risk of inducing alloimmunization, GTX are recommended only when infections are clearly unresponsive to antimicrobial drugs.

Neonates are unusually susceptible to severe bacterial infections, and a number of defects of neonatal body defenses may be contributing factors (see Chapter 98). These abnormalities are accentuated in sick premature neonates, and it is logical to

consider GTX. Neonates exhibiting fulminant sepsis, relative neutropenia ($<3.0 \times 10^9$ /L during the first week of life; $<1.0 \times 10^9$ /L thereafter), and a severely diminished neutrophil marrow storage pool (<10% of nucleated marrow cells being postmitotic neutrophils) are at particularly great risk of dying if only treated with antibiotics. Although some studies have shown a significant benefit from GTX, they are rarely used. Instead, some neonatologists consider alternative therapies including intravenous immunoglobulin (IVIG) and recombinant myeloid growth factors (G-CSF or granulocyte-macrophage colony-stimulating factor [GM-CSF]). Results of studies evaluating IVIG have been mixed, but a meta-analysis found significant benefit for neonates with proven sepsis. Current data are insufficient to determine whether recombinant myeloid growth factors have a role in treating these neonates, although both G-CSF and GM-CSF have been demonstrated to enhance myelopoiesis and to increase neutrophil blood counts in infants. Importantly, G-CSF clearly is efficacious for the treatment of several types of severe congenital neutropenia.

Once the decision to provide GTX has been made, an adequate dose of fresh leukapheresis cells must be transfused. Neonates and infants weighing less than 10?kg should receive

Box 464-1. Guidelines for Pediatric Granulocyte Transfusions

CHILDREN AND ADOLESCENTS

Neutrophils $< 0.5 \times 10^9$ /L and bacterial infection *unresponsive* to appropriate antimicrobial therapy

Qualitative neutrophil defect and infection (bacterial or fungal) *unresponsive* to appropriate antimicrobial therapy

INFANTS WITHIN FIRST 4 MO OF LIFE

Neutrophils $< 3.0 \times 10^9$ /L (1st wk of life) or $< 1.0 \times 10^9$ /L (thereafter) and *fulminant* bacterial infection

Words in *italics* must be defined for local transfusion guidelines.

$1–2 \times 10^9$ /kg neutrophils per GTX. Larger infants and children should receive a total dose of at least 1×10^{10} neutrophils per each GTX; the preferred dose for adolescents is $5–8 \times 10^{10}$ per GTX—a dose requiring donors to be stimulated with G-CSF. GTX should be given daily until either the infection resolves or the blood neutrophil count exceeds 1.0×10^9 /L for a few days.

Chapter 465 - Fresh Frozen Plasma Transfusions

Guidelines for fresh frozen plasma (FFP) transfusions in children (Box 465–1) are similar to those for adults. FFP is transfused to replace clinically significant deficiencies of plasma proteins for which more highly purified concentrates are not available. Requirements for FFP vary with the specific factor being replaced, but a starting dose of 15?mL/kg is usually satisfactory. Transfusion of FFP is efficacious for the treatment of deficiencies of clotting factors II, V, X, and XI. Factor XIII and fibrinogen deficiencies are treated with cryoprecipitate. Transfusion of FFP is no longer recommended for treatment of patients with severe hemophilia A or B or for factor VII deficiency because safer factor VIII, IX, and VII concentrates are available. Moreover, mild to moderate hemophilia A and certain types of von Willebrand's disease can be treated with desmopressin (see Chapter 469). An important use of FFP, albeit rare in children, is for rapid reversal of warfarin effects in patients who are actively bleeding or who require emergency surgery (i.e., in whom functional deficiencies of factors II, VII, IX, and X cannot be rapidly reversed by vitamin K). Results of screening coagulation tests (prothrombin, activated partial thromboplastin, and thrombin times) should not be assumed, by themselves, to reflect the integrity of the coagulation system. To justify FFP transfusions, coagulation test results must be related to the clinical condition of the patient. Transfusion of FFP in patients with chronic liver disease and prolonged clotting times is not recommended unless bleeding is present or an invasive procedure is planned.

Although its major benefit has been in the treatment of bleeding associated with clotting factor deficiencies, FFP also contains several anticoagulant proteins (antithrombin III, protein C, and protein S), whose deficiencies have been associated with thrombosis. In selected situations, FFP may be appropriate as replacement therapy—along with anticoagulant treatment—in patients with these disorders. However, when available, purified concentrates are preferred. Other indications for FFP include replacement fluid during plasma exchange in patients with thrombotic thrombocytopenic purpura or other disorders for which FFP is likely to be beneficial (e.g., plasma exchange in a patient with bleeding and a severe coagulopathy). FFP is not indicated for correction of hypovolemia or as immunoglobulin replacement therapy, because safer alternatives exist (e.g., albumin solutions and intravenous immunoglobulin, respectively).

In *neonates*, FFP transfusions merit special considerations. Clotting times are prolonged, owing to developmental deficiency of clotting proteins, and FFP should be transfused only after reference to normal values expected for the birthweight and age of the infant in question. The indications for FFP in neonates include (1) reconstitution of red blood cell (RBC) concentrates to simulate whole blood for use in massive transfusions (e.g., exchange transfusion or cardiovascular surgery), (2) hemorrhage secondary to vitamin K deficiency, (3) disseminated intravascular coagulation with bleeding, and (4) bleeding

Box 465-1. Guidelines for Pediatric FFP Transfusions

INFANTS, CHILDREN, ADOLESCENTS

- *Severe* clotting factor deficiency and bleeding

- Plasma exchange replacement fluid for thrombotic thrombocytopenic purpura

AT-III = antithrombin III.

Words in *italics* must be defined for local transfusion guidelines.

in congenital coagulation factor deficiency when more specific treatment is either unavailable or inappropriate. The use of prophylactic FFP transfusions to prevent intraventricular hemorrhage in premature infants is not recommended. FFP should not be used as a suspending agent to adjust the hematocrit values of RBC concentrates before small-volume RBC transfusions to neonates because it offers no apparent medical benefit over the use of sterile solutions for this purpose. Similarly, the use of FFP in partial exchange transfusion for the treatment of neonatal hyperviscosity syndrome is unnecessary because safer colloid solutions are available.

When treating bleeding infants, cryoprecipitate is often considered because of its

small infusion volume. However, cryoprecipitate contains only fibrinogen and factors VIII and XIII. Thus, it is not effective for treating the usual clinical situation in bleeding infants of multiple clotting factor deficiencies despite the convenience of a small infusion volume. In preliminary studies, infusions of very small volumes of recombinant activated factor VII have been life saving with hemorrhage due to several mechanisms.

Chapter 466 - Risks of Blood Transfusions

Although the risks of allogeneic blood transfusions are extraordinarily low, transfusions must be given judiciously. Actual infectious disease risks are too low to be known accurately, but taking nucleic amplification testing and all other donor screening activities into account, a current estimate for risk of transfusion-associated HIV is 1/1 million donor exposures, with estimates ranging from 1/800,000 to 1/2 million donor exposures. Similarly, the risk of viral hepatitis C is 1/1 million donor exposures. Transfusion-associated cytomegalovirus can be nearly eliminated by transfusing leukocyte-reduced cellular blood products or by selecting blood from donors seronegative for antibody to cytomegalovirus. Additional infectious risks include other types of hepatitis and retroviruses, syphilis, parvovirus B19, Epstein-Barr virus, and Chagas disease.

Transfusion-associated risks of a noninfectious nature that may occur include fluid overload, graft versus host disease, electrolyte and acid-base imbalances, iron overload, increased susceptibility to oxidant damage, exposure to plasticizers, hemolysis when T-antigen activation of red blood cells (RBCs) has occurred, immunosuppression, and alloimmunization. Curiously, alloimmunization to RBC and leukocyte antigens seems to be very uncommon in infants. Some adverse effects are seen only in massive transfusion settings such as exchange transfusions, when relatively large quantities of blood are needed, and are rare with the small-volume transfusions usually given.

Premature infants are known to have immune dysfunction, but their relative risk of post-transfusion graft versus host disease is controversial. The postnatal age of the infant, the number of immunocompetent lymphocytes in the transfusion product, the degree of human leukocyte antigen (HLA) compatibility between donor and recipient, and other poorly described phenomena determine which infants are truly at risk. Regardless, many centers caring for preterm infants transfuse exclusively gamma-irradiated cellular products. Directed donations with blood drawn from blood relatives should always be irradiated because of the risk of engraftment with transfused HLA homozygous haploidentical lymphocytes. Cellular blood products given as intrauterine and exchange transfusions are gamma irradiated, as are transfusions for patients with severe congenital immunodeficiency disorders and recipients of hematopoietic progenitor cell transplants. Other groups potentially at risk, but for whom no conclusive data are available, are patients given T-cell antibody therapy (antithymocyte globulin or OKT3), organ allografts, immunosuppressive drug regimens, and patients infected with HIV.

Current practice uses gamma irradiation from a cesium, cobalt, or linear acceleration source at doses ranging from 2,500–5,000 cGy; a minimum dose of 2,500 cGy is required. All cellular blood components should be irradiated, but frozen “acellular”

products such as plasma and cryoprecipitate do not require it. Leukocyte reduction cannot be substituted for gamma irradiation to prevent graft versus host disease.

When blood vessels are injured, hemostasis maintains vascular integrity or causes blood flow to cease through the injured vessel. If clotting is impaired, hemorrhage occurs. If clotting is excessive, thrombosis and its complications occur. The hemostatic response needs to be rapid and regulated. Trivial trauma should not trigger a systemic reaction but must initiate a rapid, localized response. Once clotting begins, anticoagulants must confine the clotting process to the site of injury to prevent extensive thrombosis. The clot must then be physiologically lysed to re-establish blood vessel patency. These hemostatic mechanisms are very complex and involve local reactions of the blood vessel, the multiple activities of the platelet, the interaction of specific coagulation factors both with each other and with platelets, the regulation of clotting by anticoagulant factors and their inhibitors, and the factors that initiate and regulate the fibrinolytic process.

The vascular endothelium is the primary barrier against hemorrhage. When small vessels are transected, active vasoconstriction minimizes the local hemorrhage even without activation of clotting. Platelets are essential for the control of hemorrhage from small blood vessels. More extensive injury (involvement of large blood vessels) requires the participation and coordination of the full hemostatic process to provide a firm, stable, fibrin clot. The extent of this clotting is localized by the anticoagulation system; the removal of the clot requires appropriate fibrinolysis.

Isolated deficiencies of individual anticoagulants (clotting factor inhibitors) predispose the patient to excessive thrombosis. In acquired hemostatic disorders, there are frequently multiple problems with homeostasis that perturb and dysregulate hemostasis. As an example, a primary illness (sepsis) and its secondary effects (shock, acidosis) activate coagulation and fibrinolysis and impair the host's ability to restore normal hemostatic function. In disseminated intravascular coagulation (DIC), procoagulant clotting factors and anticoagulant proteins are consumed, leaving the hemostatic system unbalanced and prone to bleeding or clotting. Similarly, newborn infants or patients with severe liver disease have synthetic deficiencies of both procoagulant and anticoagulant proteins. Such dysregulation causes the patient to be predisposed to both hemorrhage and thrombosis with mild or moderate triggers that result in major alterations in the hemostatic process.

Chapter 467 - Hemostasis

467.1 Hemostatic Mechanism

The classic hemostatic mechanism includes the vascular response, platelet adhesion, platelet aggregation, clot formation, clot stabilization, limitation of clotting to the site of injury by regulatory anticoagulants, and re-establishment of vascular patency through fibrinolysis and vascular healing. The laboratory evaluation of this mechanism requires the isolated study of this response as a series of independent events; however, in vivo, these events are tightly integrated. For example, fibrinogen serves as the ligand between platelets during platelet aggregation and also serves as the substrate for thrombin that forms the fibrin clot. von Willebrand factor (VWF) provides another example of a single protein with multiple functions. It circulates in a complex with factor VIII, with VWF serving as the adhesive ligand for platelet adhesion and factor VIII serving as one of the major regulating cofactors controlling clotting. The hemostatic mechanism is further complicated in that in vivo the interactions may utilize different pathways from those studied in clinical laboratory testing. In vitro clotting is characterized by using the activated partial thromboplastin time (PTT) and the prothrombin time (PT). The PT measures the clotting process through the addition of tissue factor, which, together with factor VII, activates factor X (Fig. 467–1). In vivo, factor VIIa activates factor X and factor IX, but as routinely studied in the clinical laboratory, the pathway through which factor VIIa activates factor IX is not evaluated. If the tissue factor/factor VIIa complex activated only factor X, it would be difficult to explain why the most severe bleeding disorders are factor VIII (hemophilia A) and factor IX (hemophilia B) deficiency. Nevertheless, the mechanisms studied by the PTT and the PT permit us to evaluate clotting factor deficiencies even though these pathways may not be the same as those occurring physiologically.

After vascular injury, vasoconstriction occurs and flowing blood is subjected to exposure to the subendothelial matrix (Fig. 467–2). VWF in flowing blood contacts the subendothelial matrix proteins, changes conformation, and provides the glue to which the platelet VWF receptor binds. After adherence, platelets become activated and release storage granules containing adenosine diphosphate (ADP), thromboxane A_2 , and other stored proteins. These result in the aggregation and recruitment of other platelets to the platelet plug. Aggregation involves the interaction of specific receptors on the platelet surface with plasma hemostatic proteins, primarily fibrinogen. During the process of platelet activation, internalized platelet phospholipids (primarily phosphatidylserine) become externalized and interact at two specific, rate-limiting steps in the clotting process—those involving the cofactors factor VIII (X-ase complex) and factor V (prothrombinase complex). Vascular injury also releases tissue factor and alters the vascular surface that initiates the clotting cascade and results in the generation of the fibrin clot. The stable fibrin-platelet plug is ultimately formed through clot retraction and cross linking of the fibrin clot by factor XIII.

Examination of the interaction of clotting factors shown in Figure 467–1 discloses what has been termed the *waterfall cascade*. Inactive clotting factors denoted by roman numerals become activated. The activated clotting factor then initiates the activation of the next sequential clotting factor in a systematic manner. This results in the amplification of the process to give a burst of clotting where it is physiologically needed. In vivo, autocatalysis of factor VII generates small amounts of factor VII continuously so the system is always poised to act. Clotting is held in check by the coagulation inhibitory proteins. The release of tissue factor at the site of vascular injury generates an over thousandfold increase in factor VIIa generation. Activated platelets at the site of injury provide the membrane surface upon which the activated clotting factor, its substrate (next in the waterfall), and its cofactor all localize in close proximity to maximize the efficiency of the reactions and provide a burst of clotting where it is needed. Once generated, thrombin amplifies these reactions by providing a positive feedback loop by activating additional molecules of factors XI, VIII, and V as well as aggregating additional platelets.

In the clinical laboratory, factor XII is activated using a surface (silica or glass) or a contact activator, such as ellagic acid. Factor VII is activated and interacts with tissue factor through a similar cascade. The former is the pathway measured by the PTT and the latter that measured by the PT. This process is accelerated by the interaction with phospholipid and calcium at the steps involving factor VIII and factor V. Deficiencies of clotting factors

Figure 467.1-1 Clotting cascade with sequential activation and amplification of clot formation. Many of the factors are activated by the clotting factor above them in the cascade. The activated factors are designated by the addition of an "a." *Right side*, The major anticoagulants and the sites that they regulate (TFPI regulates TF and VIIa; protein C and S regulate factors VIII and V; and AT-III regulates Xa and thrombin [Xa]). The dotted line illustrates that in vivo TF and VIIa activate both IX and X, but in vitro we measure only the activation of factor X. Unactivated factor VIII, when bound to its carrier protein, von Willebrand factor, is protected from protein C inactivation. When thrombin or Xa activates factor VII, it becomes unbound to von Willebrand factor, where it can participate with IXa in the activation of factor X in the presence of phospholipid and calcium. Factor XIII cross links the fibrin clot and thereby makes it more stable. HMWK = high molecular weight kininogen; PL = phospholipid; Ca^{++} = calcium; TF = tissue factor; TFPI = tissue factor pathway inhibitor; P-C/S = protein C and protein S; AT-III = antithrombin III.

result in either isolated prolongation of the PTT or PT or an alteration in both. This is useful in determining hereditary clotting factor deficiencies; in acquired hemostatic disorders encountered in clinical practice, however, more than one clotting factor is frequently deficient so that the relative prolongation of the PTT and PT must be assessed.

Because clotting factors were named in the order of discovery they do not necessarily reflect the sequential order of activation (Table 467–1). In fact, factors III, IV, and VI were not subsequently found to be independent proteins, and thus these terms are no longer used. The dual mechanisms of activating clotting have been termed the *intrinsic* (surface activation) and *extrinsic* (tissue factor–mediated) pathways. The intrinsic pathway involves the initial activation of factor XII, which is accelerated by two other plasma proteins, prekallikrein and high molecular weight kininogen. Activated factor XII (XIIa), in turn, activates XI to XIa, which then catalyzes IX to IXa. On the platelet phospholipid surface, factor IXa complexes with

factor VIII and calcium to activate factor X (the “tenase” complex). The extrinsic system is measured by the prothrombin time. Addition of tissue factor causes a burst of factor VIIa generation. The tissue factor/factor VIIa complex activates factor X. This is the in vitro pathway, but in vivo the complex between tissue factor and factor VIIa triggers activation of factor IX. Whether factor X is activated by the intrinsic or the extrinsic pathway, Xa is generated. On the platelet phospholipid surface, Xa complexes with factor V and calcium (the “prothrombinase” complex) to activate prothrombin to thrombin (also referred to as IIa). Once thrombin is generated, fibrinogen is converted to a fibrin clot. This loose fibrin clot is then cross-linked by factor XIII (transglutaminase). Figure 467–1 is oversimplified because Xa can activate both factor VIII and factor V, and thrombin can activate factor V, factor VIII, factor XI, and platelets. After thrombin activates the procoagulant system, thrombin binds to thrombomodulin on the intact endothelial cell surface, where it activates the anticoagulant system. Thrombomodulin-bound thrombin is no longer a procoagulant but acts as an anticoagulant by activating protein C. Activated protein C inactivates factor V and factor VIII, which, in turn, limit further thrombin generation. Thus, when thrombin encounters intact healthy endothelium, it now functions to activate the anticoagulant mechanism and limit clotting.

Virtually all procoagulant proteins are balanced by an anticoagulant protein that regulates or inhibits procoagulant function. There are four clinically important, naturally occurring anticoagulants that regulate the extension of the clotting process. These include antithrombin III (AT III), protein C, protein S, and tissue factor pathway inhibitor (TFPI). The primary action of antithrombin III is to regulate factor Xa and thrombin. It may also serve to regulate IXa, XIa, and XIIa, but this activity is less important. Protein C, in the presence of thrombin bound to thrombomodulin, becomes activated protein C (APC). In the presence of the cofactor protein S, activated protein C proteolyses and inactivates activated factor V and activated factor VIII. The final inhibitor is TFPI, which quickly shuts down the activation of factor X by factor VII and tissue factor and shifts the activation site of tissue factor and factor VII to that of factor IX (see Figs. 467–1 and 467–2).

Once a stable fibrin-platelet plug is formed, the fibrinolytic system limits its extension and also lyses the clot (fibrinolysis) to re-establish vascular integrity. Plasmin, generated from plasminogen by either urokinase-like or tissue-type plasminogen activator, degrades the fibrin clot. In the process of dissolving the fibrin clot, fibrin degradation products are produced. This pathway is regulated by plasminogen activator inhibitors (PAI-1) and a_2 -antiplasmin.

Figure 467.1-2 Diagrammatic representation of the hemostatic mechanism. PGI_2 = prostacyclin; NO = nitric oxide; ADP = adenosine diphosphate; Epi = epinephrine; TXA_2 = thromboxane A_2 ; PAI = plasminogen activator inhibitor; GAGs = glycosaminoglycans; TAFI = thrombin activated fibrinolytic inhibitor.

TABLE 467.1-1 -- **The Coagulation Factors**

Clotting Factors	Synonym	Disorder
I	Fibrinogen	Congenital deficiency(afibrinogenemia) and dysfunction(dysfibrinogenemia)
II	Prothrombin	Congenital deficiency or dysfunction
V	Labile factor, proaccelerin	Congenital deficiency (parahemophilia)
VII	Stable factor or proconvertin	Congenital deficiency
VIII	Antihemophilic factor (AHF)	Congenital deficiency is hemophilia A (classic hemophilia)
IX	Christmas factor	Congenital deficiency is hemophilia B
X	Stuart-Prower factor	Congenital deficiency
XI	Plasma thromboplastin antecedent	Congenital deficiency, sometimes referred to as hemophilia C
XII	Hageman factor	Congenital deficiency is not associated with clinical symptoms
XIII	Fibrin-stabilizing factor	Congenital deficiency

467.2 The Clinical and Laboratory Evaluation

History.

For most hemostatic disorders, whether they be hemorrhagic or thrombotic, the clinical history provides the most useful information. For a hemorrhagic condition the history should determine the site or sites of bleeding, the severity and duration of hemorrhage, and the age at symptom onset. Was the bleeding spontaneous or after trauma? Was there a previous personal or family history of similar problems? One should determine if symptoms correlate with the degree of injury or trauma. Does bruising occur spontaneously? Are there lumps with bruises for which there is minimal trauma? If there has been previous surgery or significant dental procedures, was there any increased bleeding? If a child or adolescent has had surgery to mucosal surfaces, such as a tonsillectomy or major dental extractions, the absence of bleeding usually rules out a hereditary bleeding disorder. Delayed or slow healing of superficial injuries may suggest a hereditary bleeding disorder. In postpubertal

females, it is important to take a careful menstrual history. Because some

common bleeding disorders such as von Willebrand disease have a fairly high prevalence, mothers and family members may have the same mild bleeding disorder and may not be cognizant that the child menstrual history is abnormal. Women with mild von Willebrand disease who have a moderate history of bruising frequently have a reduction of that bruising during pregnancy or after administration of birth control pills. Medications such as aspirin and other nonsteroidal anti-inflammatory drugs may inhibit platelet function and increase bleeding symptoms in patients with a low platelet count or abnormal hemostasis.

Once the child is beyond the neonatal period, thrombotic symptoms are relatively rare until adulthood. If a child or teenager presents with deep venous thrombosis or pulmonary emboli, a detailed family history needs to be obtained to evaluate for premature thrombosis, myocardial infarction, deep venous thrombosis, or stroke in other family members. In the neonate, physiologic deficiencies of procoagulants and anticoagulants cause the hemostatic mechanism to be dysregulated, and clinical events can lead to either hemorrhage or thrombosis. Even in the absence of a family history, the presence of thrombosis in the child or teenager should trigger an evaluation of the individual for a hereditary or acquired predisposition to thrombosis.

Physical Examination.

The physical examination should focus on whether symptoms are primarily associated with the mucous membranes or skin (mucocutaneous bleeding) or the muscles and joints (deep bleeding). The examination should determine the presence of petechiae, ecchymoses, hematomas, hemarthroses, or mucous membrane bleeding. Patients with defects in platelet/blood vessel wall interaction (von Willebrand disease or platelet function defects) usually have mucous membrane bleeding (epistaxis, menorrhagia, hematuria, gastrointestinal bleeding); petechiae on the skin and mucous membranes; and small, ecchymotic lesions of the skin sometimes associated with hematomas. Individuals with a clotting factor deficiency such as factor VIII or factor IX deficiency have symptoms of deep bleeding into muscles and joints with much more extensive ecchymoses and hematoma formation. Patients with mild von Willebrand disease or other mild bleeding disorders may have no abnormal findings on physical examination.

Patients at risk for thrombotic disorders should be evaluated for swollen, warm, tender extremities or internal organs (venous thrombosis), unexplained dyspnea or persistent pneumonia especially in the absence of fever (pulmonary emboli), as well as varicosities and postphlebitic changes. Arterial thrombi usually cause an acute, dramatic impairment of organ function: stroke, myocardial infarction, and a painful white, cold extremity.

Laboratory Tests.

Patients who have a positive bleeding history or who are actively hemorrhaging should have a platelet count, bleeding time, PTT, and PT. If the results are normal, a thrombin time and VWF testing should be considered. In individuals with abnormal screening tests, further specific factor work-up should be undertaken. In a patient with an abnormal bleeding history and a positive family history, normal screening tests should not preclude further laboratory evaluation.

There are no effective routine screening tests for hereditary thrombotic disorders. If the family history is positive or the clinical thrombosis is unexplained, specific anticoagulant assays should be undertaken. Thrombosis is rare in children, and, when present, the possibility of a hereditary predisposition must be considered and evaluated in the laboratory.

BLEEDING TIME.

The bleeding time assesses the function of platelets and their interaction with the vascular wall. Disposable standardized devices have been developed that control the length and depth of the skin incision. A blood pressure cuff is applied to the upper arm and inflated to 40?mm Hg for children and adults. In term newborns and younger children a modified device has been developed and used with a lower blood pressure cuff pressure. The bleeding time is a difficult laboratory test to standardize, and there is much interlaboratory and interindividual variation. Although platelet counts less than 100,000/mm^3 are associated with prolonged bleeding times, disproportionate prolongation of the bleeding times may suggest a qualitative platelet defect or von Willebrand disease. After the incision with the bleeding time device, blood is blotted from the margin of the incision at 30?sec intervals until bleeding ceases. Although each laboratory must establish its own normal range, bleeding usually stops within 4–8?min.

PLATELET FUNCTION ANALYZER.

In an attempt to measure the early stages of hemostasis to evaluate shear, collagen binding, VWF-mediated adhesion, and platelet function, a number of in vitro platelet analyzers have been developed. The greatest experience has been with the platelet function analyzer, or PFA. The PFA has been demonstrated to have a great deal of sensitivity—particularly in the detection of VWD and some platelet function defects. The PFA is sensitive to VWD in those variants characterized by a reduction in VWF antigen or activity (see Chapter 469). There remain concerns about the specificity. Thus, further studies are warranted to establish whether the PFA can be used as a screening tool.

PLATELET COUNT.

The platelet count is essential in the evaluation of the child with a positive bleeding history because thrombocytopenia is the most common acquired cause of a bleeding diathesis in children. Patients with a platelet count above 50,000/mm^3 rarely have significant clinical bleeding. Thrombocytosis in children is usually reactive and not associated with bleeding or thrombotic complications. Persistent, severe thrombocytosis in the absence of an underlying illness may require an evaluation for the very rare pediatric presentation of essential thrombocythemia or polycythemia vera.

"ACTIVATED" PARTIAL THROMBOPLASTIN TIME (PTT).

The PTT as performed in the clinical laboratory is actually an "activated" PTT (or APTT); most refer to it as the PTT. This test measures the initiation of clotting at the level of factor XII through sequential steps to the final clot end-point. It does not measure factor VII, factor XIII, or anticoagulants. The PTT employs a contact activator (silica, kaolin, or ellagic acid) in the presence of calcium and phospholipid. Because of different reagents and laboratory instruments the normal range for the PTT varies between one hospital laboratory and another. Normal ranges are much more variable from laboratory to laboratory than with the PT.

PROTHROMBIN TIME (PT).

The PT measures the extrinsic clotting system after the activation of clotting by tissue factor (thromboplastin) in the presence of calcium. It is not prolonged with deficiencies of factors VIII, IX, XI, or XII. In most laboratories the normal PT ranges between 10–13?sec. The PT has been standardized using the International Normalized Ratio (INR) so that values can be compared from one laboratory or instrument to another. The INR is used to determine similar degrees of anticoagulation with warfarin (Coumadin)–like medications.

THROMBIN TIME.

The thrombin time measures the final step of the clotting cascade in which fibrinogen is converted to fibrin. The normal thrombin time varies between laboratories but is usually between 11–15?sec. Prolongation of the thrombin time occurs with reduced fibrinogen levels (hypofibrinogenemia or afibrinogenemia), with dysfunctional fibrinogen (dysfibrinogenemia), or by substances that interfere with fibrin polymerization, such as heparin or fibrin split products. If heparin contamination is a potential cause for a long thrombin time, a reptilase time is usually ordered.

REPTILASE TIME.

The reptilase time uses a snake venom to clot fibrinogen. Unlike the thrombin time, the reptilase time is not sensitive to heparin and is prolonged only by reduced or dysfunctional fibrinogen and fibrin split products. Therefore, if the thrombin time is prolonged but the reptilase time is normal, the prolonged thrombin time is due to heparin and does not

TABLE 467.2- 2 -- Reference Values for Coagulation Tests in Healthy Children[*]

Data from Andrew M, Paes B, Johnston M: Development of the hemostatic system in the neonate young infant. Am J Pediatr Hematol Oncol 1990; 12: 95; and Andrew M, Vegh P, Johnston M, et a Maturation of the hemostatic system during childhood. Blood 1992; 80: 1998.

* *All factors except fibrinogen are presented as units/ mL (fibrinogen in mg/ mL), where pooled normal plasma contains 1 unit/ mL. All data are expressed as the mean followed by the upper and lower boundaries encompassing 95% of the normal population.*
‡ *Values are significantly different from those of adults.*
§ *Values are significantly different from those of full- term infants.*
† *Levels for 19– 27 wk and 28– 31 wk are from multiple sources and cannot be analyzed statistically. Value given as CTA units/ mL.*

indicate the presence of fibrin split products or reduced concentration or function of fibrinogen.

MIXING STUDIES.

If there is an unexplained prolongation of the PT, PTT, or thrombin time, a mixing study is usually performed. Normal plasma is added to the patient's plasma, and the PTT or PT is repeated. Correction of the PT or PTT by 1:1 mixing with normal plasma suggests the deficiencies of a clotting factor, since a 50% level of individual clotting proteins is sufficient to produce a normal PT or PTT. If the clotting time is not corrected or only partially corrected, an inhibitor is usually present. In the inpatient setting, the most common cause of this finding is heparin contamination of the sample. The presence of heparin in the sample can be ruled in or out using the thrombin time and reptilase time as noted earlier. If the mixing study does not correct or becomes more prolonged and the patient has clinical bleeding, an inhibitor (antibody directed against) of a specific clotting factor, most commonly factor VIII, or IX or XI, may be present. If the patient has no bleeding symptoms and both the PTT and the mixing study are prolonged, a lupus-like anticoagulant (see Chapter 474) is often present. These patients usually have a long PTT, do not bleed, and may have a clinical predisposition to excessive clotting.

CLOTTING FACTOR ASSAYS.

Each of the clotting factors can be measured in the clinical laboratory using individual factor-deficient plasmas. For most clotting factors, their activity is measured against a pooled normal plasma or standard where 100% activity is expressed as 100?U/dL. In general, severe deficiency of factor VIII or factor IX is less than 1?U/dL of normal plasma (< 1% of normal), moderate deficiency between 1–5?U/dL of normal, and mild deficiencies greater than 5?U/dL but below the normal range. For most clotting factors the normal range is between 50–150?U/dL (50–150%).

In patients with hemophilia A or hemophilia B, inhibitors of factor VIII or factor IX may develop after exposure to replacement therapy. To quantitate the amount of inhibitor present, the standardized clinical assay of these clotting inhibitors is termed the *Bethesda assay*. One Bethesda unit is defined as the amount that will inhibit 50% of the clotting factor in normal plasma.

PLATELET AGGREGATION.

When a qualitative platelet function defect is suspected, platelet aggregation testing is usually ordered. Platelet-rich plasma from the patient is activated with one of a series of agonists (ADP, epinephrine, collagen, thrombin or thrombin-receptor peptide, and ristocetin). Repeat testing or testing of other symptomatic family members can help determine the hereditary nature of the defect. Many medications, especially aspirin, other nonsteroidal anti-inflammatory drugs, and valproic acid alter platelet function testing. Some platelet aggregometers measure specific ADP release from the plates, as reflected in generating luminescence (lumiaggregometer) and are more sensitive in detecting abnormalities of the platelet release reaction from storage granules.

TESTING FOR THROMBOTIC PREDISPOSITION.

Hereditary predisposition to thrombosis is associated with a reduction of anticoagulant function (protein C, protein S, AT-III); presence of a factor V molecule that is resistant to inactivation by protein C (factor V Leiden); elevated procoagulants (a mutation of the prothrombin gene); or deficiency of fibrinolysis (plasminogen deficiency). If warranted by the clinical severity and history of thrombosis, specific tests of the natural anticoagulants are ordered. Whereas both immunologic and functional tests are usually available, the functional assay of protein C, protein S, and antithrombin III is more clinically useful.

Factor V Leiden is a common mutation in factor V that is associated with significant risk of thrombosis. A point mutation in the factor V molecule prevents the inactivation of activated factor V by protein C and, thereby, the persistence of activated factor V. This defect has also been termed *APC resistance* and is easily diagnosed by DNA testing.

The *prothrombin gene mutation* (*G20210A*) is a mutation in the noncoding portion of

the prothrombin gene with a G at position 20210 being replaced by an A. This mutation increases the amount of prothrombin mRNA, is associated with elevated levels of prothrombin, and causes a thrombotic predisposition. This abnormality is easily identified using molecular (DNA) diagnostic testing.

ELEVATED HOMOCYSTEINE.

Homocysteine levels may be increased as a result of genetic mutations causing homocystinuria. Such patients have a predisposition to both arterial and venous thrombosis as well as an increase in arteriosclerosis.

TESTS OF THE FIBRINOLYTIC SYSTEM.

The euglobulin clot lysis time (ELT) is used to assess a reduction of fibrinolysis. More specific tests are available in most laboratories to determine the levels of plasminogen, plasminogen activator, and inhibitors of fibrinolysis. An increase in fibrinolysis may be associated with hemorrhagic symptoms, and a delay in fibrinolysis is associated with thrombosis.

Developmental Hemostasis.

The normal newborn infant has a reduced level of most procoagulants and anticoagulants. Table 467–2 lists the levels of hemostatic proteins in the newborn and older children. In general, there is a more marked abnormality in the preterm infant. While major differences exist in the normal ranges for newborn and preterm infants, these ranges vary greatly between laboratories. During gestation there is progressive maturation and increase of the clotting factors synthesized by the liver. The extremely premature infant will have a prolonged PTT and PT as well as a marked reduction in anticoagulant proteins (proteins C, S, and AT III). Note that fibrinogen, factor V, factor VIII, VWF, and platelets are near-normal throughout the later stages of gestation (see Chapter 92.4). Because protein C and protein S are physiologically reduced, the normal factor V and factor VIII are not balanced with their regulatory proteins. In contrast, the physiologic deficiency of vitamin K–dependent procoagulant proteins (factors II, VII, IX, and X) is partially balanced by the physiologic reduction of AT III. The net effect is that newborns (especially premature infants) are at increased risk for bleeding and clotting complications or both.

Chapter 468 - Hereditary Clotting Factor Deficiencies (Bleeding Disorders)

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are the most common and serious congenital coagulation factor deficiencies. The clinical findings in hemophilia A and B are virtually identical. Hemophilia C refers to the bleeding disorder associated with reduced levels of factor XI and is discussed separately in Chapter 468.2 . The contact factors (factor XII, high molecular weight kininogen, and prekallikrein), which are associated with significant prolongation of the activated partial thromboplastin time (APTT) but are not associated with hemorrhage, are discussed in Chapter 468.3 . Other coagulation factor deficiencies that are less common are briefly discussed in subsequent subchapters.

468.1 Factor VIII or Factor IX Deficiency (Hemophilia A or B)

Factor VIII and factor IX deficiencies are the most common severe inherited bleeding disorders. Hemophilia has been recognized as a clinical entity since Biblical times; Talmudic writings permitted the avoidance of circumcision when there was a repeated history of death from circumcisional bleeding in male siblings. Whole blood or plasma was used during the mid-20th century for treatment of hemophilia. The “concentrate” era of treatment began in 1964 with the discovery that cryoprecipitate, a fraction of plasma that contained factor VIII, could be used to treat hemophilia A. Shortly thereafter, concentrates for both factor VIII and factor IX were commercially developed. In 1985 the genes for both factor VIII and factor IX were cloned. Subsequently, recombinant factor VIII and factor IX concentrates were developed to treat patients with hemophilia and thereby avoid the infectious risk of plasma-derived transfusion-transmitted diseases.

Pathophysiology.

Factor VIII and factor IX participate in a complex required for the activation of factor X. Together with phospholipid and calcium, they form the “tenase,” or factor X–activating, complex. Figure 467–1 illustrates the clotting process as it occurs in the test tube, with factor X being activated by either the complex of factor VIII and factor IX or the complex of tissue factor and factor VII. In vivo factor VII and tissue factor can also activate factor IX. This may be one reason that deficiencies of factor VIII and factor IX are the severest bleeding disorders. In the laboratory, however, the prothrombin time (PT) measures the activation of factor X by factor VII and is therefore normal in patients with factor VIII or factor IX deficiency.

After injury, the initial hemostatic event is the formation of the platelet plug together with the generation of the fibrin clot that prevents further hemorrhage. In hemophilia A or hemophilia B, clot formation is delayed and is not robust. Thus, patients with hemophilia do not bleed more rapidly. There is, instead, a slowing of the rate of clot formation. When untreated bleeding occurs in a closed space such as a joint, cessation of bleeding may be the result of tamponade. With open wounds, in which tamponade cannot occur, profuse bleeding may result in significant blood loss. The clot that is formed may be friable, and rebleeding occurs during the physiologic lysis of clots or with minimal new trauma.

Clinical Manifestations.

Neither factor VIII nor factor IX crosses the placenta; thus, bleeding symptoms may be present from birth or occur in the fetus. Occasionally, neonates with hemophilia may sustain intracranial hemorrhage. Surprisingly, only about 30% of affected male infants with hemophilia bleed with circumcision. Thus, if the family history does not alert the physician to be suspicious for its presence, hemophilia may go undiagnosed in the newborn. It is only when a child begins to crawl and walk that mobility causes the initiation of easy bruising, intramuscular hematomas, and hemarthroses. Bleeding from minor traumatic lacerations of the mouth may persist for hours or days and may cause the parents to seek medical evaluation. Even in patients with severe hemophilia, only 90% have evidence of increased bleeding by 1 yr of age. Although bleeding may occur in any area of the body, the hallmark of hemophilia is the hemarthrosis. Bleeding into joints may be induced by minor trauma; nonetheless, many hemarthroses are spontaneous. The earliest joint hemorrhages appear most commonly in the ankle, because of the lack of stability of this joint as the toddler assumes an upright posture. In the older child and adolescent, hemarthroses of the knees and elbows are the most debilitating. Whereas the child's early joint hemorrhages are recognized only after major swelling and fluid accumulation in the joint space, older children are frequently able to recognize bleeding earlier than the physician. Patients with severe hemophilia often develop a “target” joint where repetitive episodes of bleeding occur. Recurrent bleeding may then become spontaneous because of the underlying pathologic changes to the joint.

Although most muscular hemorrhages are clinically evident owing to localized pain or swelling, bleeding into the iliopsoas muscle requires specific mention. Patients may lose large volumes of blood into the iliopsoas muscle and verge on hypovolemic shock with only a vague area of referred pain in the groin. The diagnosis is made clinically by the inability to extend the hip but demands confirmation with ultrasonography or CT scan together with aggressive replacement therapy.

Life-threatening bleeding in the hemophilic patient is caused by bleeding into vital structures (central nervous system, upper airway) or by exsanguination (external, gastrointestinal, or iliopsoas hemorrhage). Prompt treatment with clotting factor concentrate for these life-threatening hemorrhages is imperative. If head trauma is of sufficient concern so as to suggest radiologic evaluation, factor replacement should precede radiologic evaluation. Life-threatening hemorrhages require replacement therapy to achieve a level equal to that of normal plasma (100?U/dL or 100%).

Patients with mild hemophilia who have factor VIII or IX levels greater than 5?U/dL

usually do not have spontaneous hemorrhages. These individuals may experience prolonged bleeding after dental work, surgery, or injuries from moderate trauma.

Laboratory Findings.

The laboratory screening test that is affected by a reduced level of factor VIII or factor IX is the APTT. In severe hemophilia, this APTT is usually two to three times the upper limits of normal. The other screening tests of the hemostatic mechanism (platelet count, bleeding time, prothrombin time, and thrombin time) are normal. Unless the patient has an inhibitor to factor VIII, the mixing of normal plasma with patient plasma results in correction of the PTT. The specific assay for factor VIII and factor IX will confirm the diagnosis of hemophilia. If correction does not occur on mixing, an inhibitor may be present. In 14–25% of patients who receive infusions of factor VIII or factor IX, a factor-specific antibody may develop. These antibodies are directed against the active clotting site and are termed *inhibitors*. In such patients the quantitative Bethesda assay for inhibitor should be performed.

Genetics and Classification.

Hemophilia occurs in approximately 1:5,000 males, with 85% having factor VIII deficiency and 10–15% having factor IX deficiency. Hemophilia shows no apparent racial predilection, appearing in all ethnic groups. The severity of hemophilia is classified on the basis of the patient's baseline level of factor VIII or factor IX because factor levels usually

---

correlate with the severity of the bleeding symptoms. By convention, 1 unit (U) of each factor is defined as the amount found in 1?mL of normal plasma, thus 100?mL of normal plasma has 100?U/dL (100% activity) of each factor. Severe hemophilia is characterized by having less than 1.0?U/dL (<1%) of the specific clotting factor, and bleeding is often spontaneous. Patients with moderate hemophilia have 1–5?U/dL and require mild trauma to induce bleeding. Individuals with mild hemophilia have levels greater than 5?U/dL, may go many years before the condition is diagnosed, and frequently require significant trauma to cause bleeding. The hemostatic level for factor VIII is more than 30–40?U/dL, and for factor IX it is more than 25–30?U/dL.

The genes for both factor VIII and factor IX are carried near the terminus of the long arm of the X chromosome and are therefore X-linked traits. The majority of patients have reduction in the amount of clotting factor protein; however, 5–10% of hemophilia A and 40–50% of hemophilia B patients make a dysfunctional protein. One specific genetic mutation in hemophilia A warrants further discussion. Forty-five to 50% of patients with severe hemophilia A have the same mutation, in which there is an internal inversion within the factor VIII gene that results in no protein being produced. This mutation can be detected in the blood of patients or carriers and in the amniotic fluid by molecular techniques. Because of the multiple genetic causes of either factor VIII or factor IX deficiency, however, most patients are classified based on the amount of factor VIII or factor IX clotting activity. In the newborn, factor VIII levels may be artificially elevated because of the acute-phase response elicited by the birth process. This may cause a mildly affected patient to have normal or near-normal levels of factor VIII. Patients with severe hemophilia will not have detectable levels. In contrast, factor IX levels are physiologically low in the newborn. If severe hemophilia is present in the family, an undetectable level of factor IX is diagnostic of severe hemophilia B. Sometimes with mild factor IX deficiency, the presence of hemophilia can be confirmed only after several weeks of life.

Some female carriers of hemophilia A or hemophilia B will have sufficient reduction of their factor VIII or factor IX through lionization of the X chromosome to produce mild bleeding disorders in carriers. Factor VIII or factor IX levels should be determined in all known carriers to assess the need for treatment in the event of surgery or clinical bleeding.

Because factor VIII is carried in plasma by von Willebrand factor (VWF), the ratio of factor VIII to VWF is sometimes used to diagnose carriers of hemophilia. When possible, specific genetic mutations should be identified in the propositus and used to test other family members at risk for either having hemophilia or being carriers.

Treatment.

The prevention of trauma is important to the care of the child with hemophilia, but hemorrhages may occur in the absence of trauma. Early psychosocial intervention helps the family achieve a balance between overprotection and permissiveness. Aspirin and other nonsteroidal anti-inflammatory drugs that affect platelet function should be avoided by patients with hemophilia. Although recombinant products may avoid exposure to transfusion-transmitted diseases, the infant should be immunized against hepatitis B virus in the neonatal period in case plasma-derived products are used with future hemorrhages. Patients should be periodically screened for hepatitis and abnormalities in liver function. Calculation of the dose of recombinant factor VIII (FVIII) or recombinant factor IX (FIX) is as follows: * †

REPLACEMENT THERAPY.

When bleeding occurs, levels of factor VIII or IX must be raised to hemostatic levels (35–40?U/dL) or for life-threatening or major hemorrhages to 100?U/dL (100%). Table 468–1 summarizes the treatment of some common types of hemorrhage in a patient with hemophilia.

With the availability of recombinant replacement products, prophylaxis has been recommended for many young children with severe hemophilia to prevent spontaneous bleeding and early joint deformities. The results of prophylaxis have been impressive in the prevention of chronic joint disease. If patients develop target joints, “secondary” prophylaxis is often initiated.

With mild factor VIII hemophilia, the patient's endogenously produced factor VIII can be released by the administration of desmopressin acetate. In patients with moderate or severe factor VIII deficiency, the stored levels of factor VIII in the body are inadequate, and desmopressin treatment is ineffective. On the other hand, exposing the patient with mild hemophilia to transfusion-transmitted diseases or the

cost of recombinant products warrants the use of desmopressin if it is effective. Stimate, a concentrated intranasal form of desmopressin acetate, can also be used to treat patients with mild hemophilia A. The Stimate dose is 150?µg (one puff) for children weighing less than 50?kg and 300?µg (two puffs) for children and young adults weighing more than 50?kg. Most centers administer a trial of desmopressin to determine the level of factor VIII achieved after its infusion. Desmopressin is not effective in the treatment of factor IX–deficient hemophilia.

Prophylaxis.

Many patients are now placed on lifelong prophylaxis programs to prevent spontaneous joint bleeding. Usually, such programs are initiated with the first joint hemorrhage. Young children often require the insertion of a central catheter to ensure venous access. Such programs, although expensive, are highly effective at preventing or greatly modulating the degree of joint pathology. Treatment is usually provided every 2–3 days to maintain a measurable plasma level of clotting factor (1–2?U/dL) when assayed just before the next infusion (trough level). Because gene therapy may be available within the lifetime of pediatric patients, keeping joints normal through prophylaxis is a logical priority. If moderate arthropathy develops, prevention of future bleeding will require higher plasma levels of clotting factors and the individual will be less amenable to gene therapy. In the older child who is not placed on primary prophylaxis, secondary prophylaxis is sometimes initiated if a target joint develops.

Chronic Complications.

The long-term complications of hemophilia A and B include chronic joint destruction, the risk of transfusion-transmitted infectious diseases, and the development of an inhibitor to either factor VIII or factor IX. Although the aggressive or prophylactic approach to treatment has reduced the problems of chronic arthropathy, these problems have not been eliminated. Furthermore, whereas transfusion-transmitted diseases are minimized or negated by using highly purified or recombinant products, many older patients have been exposed to plasma-derived products. As a result, transfusion-transmitted diseases, including HIV infection and hepatitis C or B, may be the major long-term cause of morbidity and mortality in older adolescents and adults with hemophilia. The incidence of inhibitors appears similar in patients using either recombinant or plasma-derived products for factor VIII replacement. Highly purified factor IX or recombinant factor IX seems to increase the incidence of factor IX inhibitors, and some may induce anaphylaxis.

* B-domain deleted recombinant factor VIII (Refacto) may require special assays to determine plasma level—chromogenic assay or referencing versus a Refacto Standard.
† Correction factor is 1.0 for plasma-derived factor IX.

TABLE 468.1- 1 -- Treatment of Hemophilia

Type of Hemorrhage	Hemophilia A	Hemophilia B
Hemarthrosis[*]	20–40 U/kg factor VIII concentrate[‡] ; 15 U/kg if treated early. Repeat the dose daily until joint function is normal or back to baseline. Consider additional treatment every other day for 7–10 days. Consider prophylaxis.	40 U/kg factor IX concentrate ; 30 U/kg if treated early. Repeat the dose daily until joint function is normal or back to baseline. Consider additional treatment every other day for 7–10 days. Consider prophylaxis.
Muscle or significant subcutaneous hematoma	20 U/kg factor VIII concentrate; may need every-other-day treatment until resolved	40 U/kg factor IX concentrate ; may need treatment every 2–3 days until resolved
Mouth, deciduous tooth, or tooth extraction	20 U/kg factor VIII concentrate; antifibrinolytic therapy; remove loose deciduous tooth	40 U/kg factor IX concentrate ; antifibrinolytic therapy[‡] ; remove loose deciduous tooth
Epistaxis	Apply pressure for 15–20 min; pack with petrolatum gauze; antifibrinolytic therapy; 20 U/kg factor VIII concentrate if above fails	Apply pressure for 15–20 min; pack with petrolatum gauze; antifibrinolytic therapy; 30 U/kg factor IX concentrate if above fails
Major surgery, life-threatening hemorrhage (e.g., central nervous system, gastrointestinal, airway)	50–75 U/kg factor VIII concentrate, then initiate continuous infusion of 2–4 U/kg/hr to maintain factor VIII >100 U/dL for 24 hr, then give 2–3 U/kg/hr continuously for 5–7 days to maintain the level > 50 U/dL and an additional 5–7 days at a level > 30 U/dL	120 U/kg factor IX concentrate , then 50–60 U/kg every 12–24 hr to maintain factor IX > 40 U/dL for 5–7 days, and then > 30 U/dL for 5 days
Iliopsoas hemorrhage	50 U/kg factor VIII concentrate, then 25 U/kg every 12 hr until asymptomatic, then 20 U/kg every other day for total 10–14 days[§]	120 U/kg factor IX concentrate ; then 50–60 U/kg every 12–24 hr to maintain factor X > 40 U/dL until asymptomatic, then 40–50 U every other day for total 10–14 days[§] [¶] I
Hematuria	Bed rest; ½ × maintenance fluids; if not controlled in 1–2 days, 20 U/kg factor VIII concentrate; if not controlled, give prednisone (unless HIV-infected)	Bed rest: ½ × maintenance fluids; if not controlled in 1–2 days, 40 units/kg factor IX concentrate ; if not controlled, give prednisone (unless HIV-infected)
Prophylaxis	20 U/kg factor VIII concentrate every other day to achieve trough level =1%.	30 U/kg factor IX concentrate every 2–3 days to achieve trough level =1%

Adapted from Montgomery RR, Gill JC, Scott JP: Hemophilia and von Willebrand disease. In Nathan DG, Orkin SH (editors): Nathan and Oski's Hematology of Infancy and Childhood, 5th ed. Philadelphia, WB Saunders, 1998.

** For hip hemarthrosis, orthopedic evaluation for possible aspiration is advisable to prevent avascular necrosis of the femoral head.*
† For mild or moderate hemophilia, desmopressin, 0.3?µg/kg, should be used instead of factor VIII concentrate, if patient is known to respond with a hemostatic level of factor VIII; if repeated doses are given, monitor factor VIII levels for tachyphylaxis.
Stated doses apply for recombinant factor IX concentrate; for plasma- derived factor IX concentrate, use 70% of stated dose.
‡ Do not give antifibrinolytic therapy until 4– 6 hr after a dose of prothrombin complex concentrate.
§ Repeat radiologic assessment should be performed before discontinuation of therapy,
¶ If repeated doses of factor IX concentrate are required, use highly purified, specific factor IX concentrate.

Factor IX immune tolerance induction has also resulted in nephrotic syndrome in some patients.

Historically, chronic arthropathy is the major long-term disability of hemophilia. The natural history of untreated hemophilia is one of cyclical recurrent hemorrhages into specific joints, including hemorrhages into the same or “target” joint. After joint hemorrhage, proteolytic enzymes are released by white blood cells into the joint space and heme iron induces macrophage proliferation—all of which contributes to inflammation in the synovium. The synovium thickens and develops frond-like projections into the joint that are susceptible to being pinched and may induce further hemorrhage. The cartilaginous surface becomes eroded and ultimately may even expose raw bone, leaving the joint susceptible to articular fusion. When the first hemorrhages occur in a child's joints, the joint has not been previously damaged. The synovium is therefore elastic and can accommodate a large amount of blood. Frequently, the swelling is much greater than the pain. In contrast, the older patient with advanced arthropathy may have such a scarred joint that there is little space for accommodating blood. In these patients the pain is much greater than the degree of swelling. Once a target joint is seen to be developing, the patient is usually placed on short- or long-term prophylaxis to prevent progression of the arthropathy and to reduce inflammation.

Whereas infection from transfusion-transmitted diseases has been dramatically reduced by using plasma-derived products that are heat treated, immuno-purified, and chemically treated, most hemophilia centers recommend the use of recombinant products, because they are free from known human transmitted viruses. Although some of these products have been produced or even reformulated in human albumin, the risk of viral infection is theoretical. Recombinant products are being developed that contain no human or other animal protein. Although HIV infection devastated the adult hemophilic population, alteration in manufacturing practices in the early to mid 1980s has eliminated this risk. However, many adults remain with HIV infection. The experience with this “epidemic” requires that great vigilance be exercised to prevent similar unexpected infections in the future. Chronic hepatitis C and even hepatitis B remain as problems for many older patients with hemophilia, but the use of recombinant products has virtually eliminated this risk in younger patients. Parvovirus and hepatitis A are nonenveloped viruses that may escape solvent detergent treatment and heat treatment. Thus, plasma-derived products may continue to transmit these infectious agents. The potential for Creutzfeldt-Jakob disease to be transmitted through blood remains controversial but unsubstantiated.

Infusion of the deficient clotting factor may initiate an immune response in patients with either factor VIII or factor IX deficiency. Inhibitors are antibodies directed against factor VIII or factor IX that block the clotting activity. Failure of a bleeding episode to respond to appropriate replacement therapy is the usual first sign of an inhibitor. Less often they are identified during routine follow-up testing. Inhibitors develop in approximately 25% of patients with hemophilia A; the percentage is somewhat lower in patients with hemophilia B, many of whom make an inactive dysfunctional protein that renders them less susceptible to an immune response. Many patients who develop an inhibitor lose this inhibitor with continued regular infusions. Others develop a higher titer with subsequent infusions and may need to go through desensitization programs, in which high doses of factor VIII or factor IX are infused in an attempt to saturate the antibody and to permit the body to develop tolerance. If desensitization fails, bleeding episodes are treated with either activated prothrombin complex concentrates or recombinant factor VIIa. The use of these products bypasses the inhibitor in many instances but may increase the risk for thrombosis. Patients with inhibitors require referral to a hospital that cares for many such patients and has a comprehensive hemophilia program.

Comprehensive Care.

Hemophilia patients today are best managed through comprehensive hemophilia care centers. Such centers are dedicated to patient and family education as well as prevention and/or treatment of the complications of hemophilia including chronic joint disease and inhibitor development as well as infectious complications such as hepatitis C and HIV. Such centers involve a team of physicians, nurses, orthopedists, physical therapists, and psychosocial workers among others.

468.2 Factor XI Deficiency (Hemophilia C)

Factor XI deficiency is an autosomal deficiency associated with mild to moderate bleeding symptoms. It is frequently encountered in Ashkenazi Jews but has been found in many other ethnic groups. In Israel, 1–3/1,000 are homozygous for this deficiency. Sephardic Jews are rarely affected.

Although the condition is referred to as hemophilia C, the bleeding tendency is not as severe as in factor VIII or factor IX deficiency. The bleeding associated with factor XI deficiency is not correlated with the amount of factor XI. Some patients with severe deficiency may have minimal or no symptoms at the time of major surgery. Unless the patient previously had surgery without bleeding, replacement therapy should be considered and given preoperatively depending on the nature of the surgical procedure. There is no licensed concentrate of factor XI available in the United States; therefore, the physician must use fresh frozen plasma (FFP) or enroll the patient in a clinical trial of factor XI concentrate.

Minor surgeries can be controlled with local pressure; dental extractions can be monitored closely and the patient treated only if hemorrhage occurs. In a patient with homozygous deficiency of factor XI, the PTT is often longer than it is in patients with either severe factor VIII or factor IX deficiency. The paradox of fewer clinical symptoms with a longer PTT is surprising, but this is the result of factor VIIa being able to activate factor IX in vivo. The deficiency of factor XI can be confirmed by specific factor XI assays. Plasma infusions of 1?U/kg usually increase the plasma concentration by 2?U/dL. Thus, the infusion of 10–15?mL of plasma/kg will result in a plasma level of 20–30?U/dL (20–30%), a level usually sufficient to control moderate hemorrhage. Frequent infusions of plasma would be necessary to achieve higher levels of factor XI. Because the factor XI half-life is usually 48?hr or greater, maintaining adequate levels of factor XI is not usually difficult.

Chronic joint bleeding is rarely a problem, and, for most patients, factor XI deficiency is a concern only at the time of major surgery unless there is a second underlying hemostatic defect (e.g., von Willebrand disease).

468.3 Deficiencies of the Contact Factors (Nonbleeding Disorders)

Deficiencies of factor VIII, factor IX, and factor XI all cause isolated prolongation of the PTT. Deficiencies of the contact factors also prolong the PTT but are not causes of clinical bleeding. These factors include factor XII, prekallikrein, and high molecular weight kininogen. Because these contact factors function at the step of initiation of the intrinsic clotting system, the PTT is markedly prolonged when these factors are absent. Thus, one encounters the paradoxical situation in which there is an extremely prolonged PTT but no evidence of clinical bleeding. It is important that these individuals be well informed about the meaning of their clotting factor deficiency, since they do not need treatment even if major surgery is undertaken. On rare occasions, factor XII deficiency is associated with von Willebrand disease and has been termed von Willebrand San Diego. Thus, if

a patient with low factor XII level is identified who has bleeding symptoms, it is advisable to carry out screening for von Willebrand disease.

468.4 Factor VII Deficiency

Factor VII deficiency is a rare bleeding disorder that is usually detected only in the homozygous state. Individuals with this deficiency may have spontaneous intracranial hemorrhage and frequent mucocutaneous bleeding. Such patients will have a markedly prolonged PT but a normal PTT. Factor VII assays demonstrate a marked reduction of factor VII. Because the plasma half-life of factor VII is 2–4?hr, therapy with FFP is difficult and often complicated by fluid overload. A commercial concentrate of recombinant factor VIIa is now available for treating factor VIII or factor IX inhibitor patients, but this concentrate may be useful in treating patients with factor VII deficiency as well. Clinical trials are currently evaluating this approach.

Deficiencies in the Factors of the Common Pathway (X, V, II, I) Causing Prolongation of Both the PT and the PTT

468.5 Factor X Deficiency

This is a rare autosomal disorder that results in mucocutaneous and post-traumatic bleeding. This deficiency is the result of either a quantitative deficiency or a dysfunctional molecule. A reduced factor X level is associated with a prolongation of both the PT and the PTT. In patients with hereditary deficiency of factor X, factor X levels can be increased using either FFP or prothrombin complex concentrate. The half-life of factor X is approximately 30?hr, and its volume of distribution is similar to factor IX. Thus, 1?U/kg will increase the plasma level of factor X 1?U/dL (1%).

Although rarely a problem in pediatric patients, systemic amyloidosis may be associated with factor X deficiency owing to the adsorption of factor X on the amyloid protein. In the setting of amyloidosis, transfusion therapy is often not successful because of the rapid clearance of factor X.

468.6 Prothrombin (Factor II) Deficiency

This deficiency is caused either by a markedly reduced prothrombin level (hypoprothrombinemia) or by a functionally abnormal prothrombin (dysprothrombinemia). Laboratory testing in homozygous patients demonstrates a prolonged PT and PTT. Factor II or prothrombin assays demonstrate the markedly reduced prothrombin level. Treatment can be achieved using either prothrombin complex concentrates or FFP. In prothrombin deficiency, FFP is useful, because the half-life of prothrombin is 3.5 days. Administration of 1?U/kg of prothrombin will increase the plasma concentration by 1?U/dL (1%).

468.7 Factor V Deficiency

The deficiency of factor V, also known as labile factor, is an autosomal recessive, mild to moderate bleeding disorder that has also been termed *parahemophilia*. Hemarthroses occur rarely; mucocutaneous bleeding and hematomas are the most common symptoms. Severe menorrhagia is a frequent symptom in women. Laboratory evaluation demonstrates a prolonged PTT and PT. Specific assays for factor V demonstrate a reduction in factor V levels. FFP is the only currently available therapeutic product that contains factor V. Factor V is lost rapidly from FFP. It is therefore important to use FFP that is less than 2 mo old. Infusing 10?mL/kg of FFP every 12?hr can treat patients with severe factor V deficiency. Rarely, one encounters the patient with a negative family history of bleeding who has an acquired antibody to factor V. Often, these patients do not bleed because the factor V in platelets prevents excessive bleeding.

468.8 Combined Deficiency of Factors V and VIII

Combined deficiency of factor V and factor VIII has been demonstrated to be secondary to the absence of an intracellular transport protein, ERGIC-53, that is responsible for transporting factor V and factor VIII from the endoplasmic reticulum

to the Golgi compartments. ERGIC-53 is encoded on chromosome 18. The deficiency of factor VIII and factor V is not related to defective genes for those proteins but is secondary to a deficiency of a transport protein. This explains the paradoxical deficiency of two factors, one encoded on chromosome 1 and the other on the X chromosome.

468.9 Fibrinogen Deficiency

Congenital afibrinogenemia is a rare autosomal recessive disorder in which there is an absence of fibrinogen. These patients do not bleed as frequently as hemophilia patients and rarely have hemarthroses. Affected patients may present in the neonatal period with gastrointestinal hemorrhage or hematomas after vaginal delivery. In addition to marked prolongation of the PTT and PT, the thrombin time is prolonged. In the absence of a consumptive coagulopathy, an unmeasurable fibrinogen level is diagnostic. In addition to the quantitative deficiency of fibrinogen, a number of dysfunctional fibrinogens have been reported (dysfibrinogenemia). Currently, no fibrinogen concentrates are commercially available. Because the plasma half-life of fibrinogen is between 2 and 4 days, treatment with either FFP or cryoprecipitate is effective. The hemostatic level of fibrinogen is above 60?mg/dL. Each bag of cryoprecipitate contains 100–150?mg of fibrinogen. Some clinical assays for fibrinogen are inhibited by high doses of heparin. Thus, a markedly prolonged thrombin time when associated with a low fibrinogen level should be evaluated with a reptilase time. A prolonged reptilase time confirms that functional levels of fibrinogen are low and that heparin is not present.

468.10 Factor XIII Deficiency (Fibrin-Stabilizing Factor or Transglutaminase Deficiency)

Because factor XIII is responsible for the cross linking of fibrin or the stabilization of fibrin clot, symptoms of delayed hemorrhage are secondary to instability of the clot. Typically, patients will have trauma one day and then develop a bruise or hematoma on the following day. Clinical symptoms include mild bruising, delayed separation of the umbilical stump beyond 4 wk, poor wound healing, and, in women, recurrent spontaneous abortions. The usual screening tests for hemostasis are normal in patients with factor XIII deficiency. Screening tests for factor XIII deficiency are based on the observation that there is an increased solubility of the clot because of the failure of cross linking. The normal clot remains insoluble in the presence of 5 M urea, whereas the clot formed from a patient with factor XIII deficiency dissolves. More specific assays for factor XIII are immunologic. Because the half-life of factor XIII is 5–7 days and the hemostatic level is 2–3?U/dL, infusion of FFP or cryoprecipitate will correct the deficiency in these patients. Plasma contains 1?U/dL, and cryoprecipitate contains 75?U/bag. In patients with significant bleeding symptoms, prophylaxis can be achieved with infusion of cryoprecipitate every 3–4 wk.

468.11 Antiplasmin or Plasminogen Activator Inhibitor (PAI) Deficiency

Deficiency of either of these two antifibrinolytic proteins results in increased plasmin generation and the premature lysis of fibrin clots. Patients have mucocutaneous bleeding but rarely have joint hemorrhages. Because the usual hemostatic tests are normal, further work-up of a patient with a positive bleeding history should include the euglobulin clot lysis time that measures fibrinolytic activity and is shortened in the presence of these deficiencies. Specific assays for a_2 -antiplasmin and PAI are available. Treatment can be accomplished using FFP.

Chapter 469 - von Willebrand Disease

von Willebrand disease (VWD) is the most common hereditary bleeding disorder, with some reports suggesting that it is present in 1–2% of the general population. VWD is inherited autosomally, but most centers report more women than men affected. Because menorrhagia is a major symptom, it may cause more women to seek diagnosis. VWD is classified on the basis of whether the protein is quantitatively reduced but not absent (type 1), qualitatively abnormal (type 2), or absent (type 3) (Fig. 469–1). Mutations in different loci that code for different functional domains of the VWF protein cause the different variants of VWD.

Pathophysiology.

von Willebrand factor (VWF) is a large multimeric glycoprotein that is synthesized in megakaryocytes and endothelial cells and stored in a-granules and Weibel-Palade bodies, respectively. The highest molecular weight multimers of VWF are responsible for the normal interaction of VWF with the subendothelial matrix and platelets. During normal hemostasis, VWF adheres to the subendothelial matrix after vascular damage. When VWF binds to the subendothelial matrix, the conformation of VWF is changed so that it causes platelets to adhere to VWF through their glycoprotein IB (GPIb) receptor. These platelets are then activated, causing the recruitment of additional platelets and exposing phosphatidylserine, which is an important regulatory step for factor V– and factor VIII–dependent steps in the clotting cascade. VWF also serves as the carrier protein for plasma factor VIII. A severe deficiency of VWF may cause a secondary deficiency in factor VIII, even though the gene for factor VIII is normal. This is the cause of autosomal deficiency of factor VIII, now known to be a molecular abnormality of VWF and termed type 2N VWD.

Clinical Manifestations.

Patients with VWD usually have symptoms of mucocutaneous hemorrhage, including excessive bruising, epistaxis, menorrhagia, and postoperative hemorrhage, particularly after mucosal surgery such as tonsillectomy or wisdom tooth extraction. Because a teenager's menstrual history is usually put in the context of other family members, excessive menstrual bleeding is not always recognized as being abnormal, because others in the family may be affected with the same disorder. If a menstruating female presents with iron deficiency, a detailed history of bruising and other bleeding should be elicited and further hemostatic evaluation undertaken. The American College of Obstetrics and Gynecology recommends VWD testing on all teenage females with menorrhagia before initiating hormonal therapy or oral contraceptives.

Because VWF is an acute-phase protein, stress will increase its level. Thus, patients may not bleed with procedures that incur major stress, such as appendectomy and childbirth, but may bleed excessively at the time of cosmetic or mucosal surgery. Bruising symptoms may diminish during pregnancy, because the VWF levels may double or triple during pregnancy. Rarely, patients with VWD may have gastrointestinal telangiectasia. This combination results in major bleeding and accounts for numerous hospital admissions for patients with severe disease. In patients with type 3 or homozygous VWD, bleeding symptoms are much more profound. These patients are usually diagnosed early in life and may have severe epistaxis or menorrhagia that results in major blood loss and possibly shock. Rarely, patients with severe type 3 VWD have joint hemorrhages or spontaneous central nervous system hemorrhages.

Laboratory Findings.

Patients with VWD were said to have a long bleeding time and a long PTT. Nevertheless, these tests are frequently normal in patients with type 1 VWD. Therefore, normal screening tests do not preclude the diagnosis of VWD. If the history is suggestive of a bleeding disorder, VWD testing must be undertaken, including a quantitative assay for VWF antigen, VWF activity (ristocetin cofactor activity, or VWF:RCo), plasma factor VIII activity, determination of VWF structure (VWF multimers), and a platelet count. While the platelet count is usually normal in most patients, those with type 2B disease or platelet type (pseudo-VWD) may have lifelong thrombocytopenia. Figure 469–1 lists the variants of VWD and summarizes their laboratory findings.

Genetics.

Chromosome 12 contains the gene for VWF. Each of the type 2 variants listed in Figure 469–1 has specific areas of the molecule affected. The phenotype can guide the genetic diagnosis of the specific mutation. Clinical genetic testing for VWD variants is only available in a few referral laboratories.

Treatment.

Treatment of VWD is directed toward increasing the plasma level of VWF and factor VIII. Because the gene for factor VIII is normal in patients with VWD, elevating the plasma concentration of VWF will permit the normal recovery and survival of the endogenously produced factor VIII. The most common form of VWD is type 1. In these patients the synthetic drug desmopressin (DDAVP) induces the release of VWF from the endothelial cells. In some patients with type 2 variants, desmopressin may be similarly effective, but in other circumstances the released VWF is dysfunctional. Patients with VWD may fail to respond adequately to desmopressin because they release an abnormal VWF molecule (most type 2 variants), because they have type 3 disease in which there is no VWF to be released, or because they have accelerated clearance of released VWF. A small subset of children and adults, especially infants, fail to release VWF in response to DDAVP. In these circumstances replacement therapy must be used. Current replacement therapy uses plasma-derived VWF containing concentrates that also contain factor VIII. VWF distributes only to the intravascular space, because it is so large. During plasma

fractionation, VWF multimers are altered to a variable extent. Therefore, 1?U/kg will

Figure 469-1 Common variants of VWD and other related disorders. Laboratory testing is listed on the left and the results most commonly identified in patients with these conditions are shown. N is normal, ? is degree of increase, and ? is degree of decrease. A graph representing VWF multimers is shown at the bottom of each column. A lighter shade of color illustrates a reduction in staining intensity, and figure length represents the relative size of the multimers. PT-VWD = platelet-type pseudo VWD; BSS = Bernard Soulier syndrome; FVIII = factor VIII; VWF:Ag = von Willebrand antigen; VWF:RCo = ristocetin cofactor activity; BT = bleeding time; PFA = platelet function analyzer; VWF conc = VWF concentrate; Tx = treatment.

increase the plasma level by 1.5?U/dL (1.5%). The plasma half-life of both factor VIII and VWF is 12?hr, but the alteration of VWF during fractionation results in half-lives of 8–10 hours when infusing concentrates. Purified VWF concentrates or recombinant VWF concentrates (containing no factor VIII) may become available in the near future. These will be useful in presurgical management or in prophylaxis. When used for acute bleeding, however, these VWF concentrates may need to be supplemented by an infusion of recombinant factor VIII for the first infusion. Both VWF and factor VIII are required for normal hemostasis. If only VWF is replaced, the endogenous correction of the factor VIII level takes 12–24?hr. Dental extractions and sometimes nosebleeds can be managed with both desmopressin and an antifibrinolytic agent such as e-aminocaproic acid (Amicar).

VWD Variants

Type 1 VWD is the most common form and accounts for 85% of cases. Bleeding symptoms include epistaxis, bruising, and menorrhagia. If bleeding is excessive, desmopressin administration at a dose of 0.3?µg/kg given intravenously will increase the level of VWF and factor VIII by three- to fivefold. Intranasal desmopressin (Stimate) is particularly helpful for the outpatient treatment of bleeding episodes. The dose of Stimate is 150?µg (one

puff) for children weighing less than 50?kg and 300?µg (two puffs) for those weighing more than 50?kg.

Type 2A VWD is caused by the abnormal proteolysis of VWF, with only the smallest VWF multimers being present. This results in a reduction in VWF antigen with a much greater reduction in VWF activity. Although desmopressin is safe in these patients, it is not always effective, because normal multimers are not maintained in plasma. Significant bleeding should be treated with VWF replacement therapy.

Type 2B VWD may be caused by one of several mutations resulting in "hyperactive" VWF. The abnormal VWF binds spontaneously to platelets with resulting rapid clearance of VWF and platelets. The larger molecular weight multimers of VWF are preferentially cleared from the circulation, and moderate to severe thrombocytopenia is common. The laboratory diagnosis is based on demonstration that the "hyperactive" 2B VWF binds to platelets and agglutinates them at low concentrations of ristocetin, a concentration that would not agglutinate normal platelets. If one administers desmopressin to these patients, the abnormal "hyperactive" 2B VWF would be released and more profound thrombocytopenia might occur. These patients usually respond to the infusion of VWF.

Type 2M VWD is caused by mutations that result in the reduction of the platelet-binding function of VWF. The binding of this protein to factor VIII is normal, so that the factor VIII levels will be equal to the VWF levels, but the platelet-dependent interaction of VWF is reduced significantly. Desmopressin will increase VWF and factor VIII levels, but the released type 2M VWF may not have sufficient activity to cause cessation of bleeding. Thus, VWF replacement therapy may need to be employed.

Type 2N VWD is caused by the reduction of factor VIII binding by VWF. This disorder has also been termed *autosomal hemophilia*. With this variant, platelet interaction with VWF is normal but the 2N VWF binds weakly (or not at all) to factor VIII, resulting in rapid clearance of factor VIII that is weakly complexed to VWF. Thus, the factor VIII level is reduced much more than the VWF levels. Commonly, patients who have symptomatic bleeding are compound heterozygotes who have inherited a gene for type 1 VWD from one parent and one for type 2N VWD from the other. Rarely, 2N mutations are inherited from both parents and the VWF levels are normal. In the patient who is compound heterozygous of type 1 and type 2N, the one allele makes no protein and the other allele makes a functionally abnormal protein, resulting in all of the VWF being dysfunctional. Although desmopressin will release the 2N VWF, the sustained factor VIII levels occasionally may be inadequate for normal hemostasis. A trial of desmopressin is indicated to assess the response and half-life of VWF and factor VIII after infusion. VWF replacement therapy is usually effective.

Platelet type (*pseudo*-) *VWD* is actually an abnormality of the GPIb receptor on platelets. This can be considered the converse abnormality of type 2B, in that the GPIb receptor on platelets is hyperfunctional and binds plasma VWF spontaneously. This results in thrombocytopenia and a loss of high molecular weight VWF multimers that are indistinguishable from those seen in type 2B VWD. Specific testing, however, will demonstrate that this is a platelet abnormality rather than a plasma abnormality.

Type 3 VWD is the homozygous or compound heterozygous inheritance of VWF deficiency. Patients exhibit undetectable plasma levels of VWF and only low, but measurable, levels of factor VIII. These patients will have major hemorrhage but only rarely have joint hemorrhages. This severe, very rare form occurs in approximately 1:500,000 individuals. Intracranial hemorrhage, major epistaxis, and menorrhagia in women are the major features. Bleeding episodes require treatment with VWF-containing concentrates. Desmopressin is not effective.

Chapter 470 - Hereditary Predisposition to Thrombosis

Thromboses in children are frequently caused by a hereditary or acquired prothrombotic state. Over the past 20 years a large number of hereditary causes of thrombosis have been identified. The newborn infant because of the physiologic deficiency of various regulatory proteins is particularly predisposed to both hemorrhage and thrombosis. The more premature the infant, the greater the deficiency. The sick newborn infant is particularly at risk since interventions to provide support often include placement of large indwelling catheters into major veins or arteries. Those with hereditary deficiencies of anticoagulants may have major symptoms. After the neonatal period, young children seem to have some resistance to clinical thrombosis even if they have a heterozygous hereditary deficiency of an anticoagulant protein. However, when clotting is identified in the young child, particularly when the family history is abnormal, a thrombotic work-up should be initiated. In children and teenagers, thromboses are often triggered by major medical or surgical challenges.

Pathophysiology and Clinical Manifestations

The predominant anticoagulants are illustrated in Figures 467–1 and 467–2 . A hereditary predisposition to thrombosis can be caused by deficiencies of the regulatory proteins: protein C, protein S, antithrombin III, and plasminogen; synthesis of a procoagulant protein unable to be inhibited by its regulatory protein, *factor V Leiden*; elevated levels of procoagulant protein, *prothrombin mutation* (*G20210A*); and elevated levels of a toxic organic acid, homocystinuria.

The hereditary mutation of factor V, termed *factor V Leiden*, results in a factor V molecule that, when activated, is not subsequently inactivated by activated protein C. This leaves the patient with unregulated “active” factor V and so-called resistance to activated protein C. Individuals with the *prothrombin mutation* (*G20210A*) have a mutation in the 3'-untranslated end of the mRNA for prothrombin that results in increased levels of prothrombin synthesis. Children with these hereditary mutations have an increased frequency of venous thrombosis. Young women are at increased risk of venous thrombosis during pregnancy or while receiving oral contraceptive agents. There is also an increased risk of recurrent abortions. If one evaluates young adults

with thrombosis, factor V Leiden and the prothrombin mutation (G20210A) are the most common associated abnormalities.

While patients with heterozygous deficiencies may be predisposed to thrombosis, those with *homozygous protein C deficiency* have fatal purpura fulminans in the neonatal period if untreated. Such infants were probably overlooked in the past because the symptoms were thought to be secondary to sepsis and disseminated intravascular coagulation. Because the newborn is physiologically deficient in protein C, its absence is difficult to determine except in a laboratory that has established normal ranges for neonates and preterm infants. If an individual has undetectable levels of protein C, this is most likely a hereditary disorder. The physiologic deficiency of protein C in the newborn coupled with true sepsis may also lead to nearly undetectable levels of protein C.

Laboratory Findings.

There are no screening tests for hereditary deficiencies of anticoagulants such as protein C, protein S, antithrombin III, or factor V Leiden and prothrombin 20210; thus, specific testing is required. A careful family history may reveal thromboembolic diseases in family members at a young age, but the absence of a positive history does not rule out a hereditary predisposition to thrombosis. If hereditary deficiency of anticoagulant or regulatory proteins is suspected, specific assays should be undertaken. Techniques that quantitate the amount and function of antithrombin III, protein C, and free protein S are well established. Genetic DNA testing for factor V Leiden and the prothrombin mutation (G20210A) are more sensitive and specific than clotting-based tests.

Treatment.

Homozygous deficiency of protein C presents with purpura fulminans in the first few hours of life. A recombinant activated protein C concentrate has been licensed for adult sepsis, but it has not been licensed for treating hereditary deficiency. Fresh frozen plasma (FFP) is the only immediately available source of protein C. Amelioration of symptoms usually requires 10–15?mL/kg of FFP every 8–12?hr. Clinical trials are in progress using a plasma protein C concentrate, which eliminates the need for large amounts of FFP. After the infant's symptoms are reduced, the amount of FFP or protein C concentrate is adjusted and monitored by frequent protein C levels. When the infant is beyond the neonatal period, high-dose warfarin (to achieve an INR of 4–5) may prevent most of the thrombotic problems, but acute intermittent thromboses require additional FFP or protein C concentrate (see also Chapter 471). Thromboses associated with a hereditary predisposition to clotting should be treated with anticoagulants as outlined in Chapter 471 . Replacement therapy is usually not indicated. Individuals with homocystinuria should receive anticoagulation as well as management of their primary disease (see Chapter 74.3).

Chapter 471 - Acquired Thrombotic Disorders

The occlusion of a blood vessel with a platelet plug or fibrin clot may occur in vessels of any size. A large number of systemic disorders are associated with occlusion of arterial or venous vessels of diverse caliber, including vasculitic diseases like systemic lupus erythematosus and Kawasaki disease, metabolic defects like homocystinuria, and red cell disorders like sickle cell anemia and polycythemia. Activation of clotting as a complication of disseminated intravascular coagulation (DIC) can cause microvascular and macrovascular thrombosis. Medical interventions themselves can predispose to thrombosis, such as when sick newborns have indwelling catheters placed in major vessels or when children with acute lymphoblastic leukemia receive the chemotherapeutic agent L-asparaginase that depletes anticoagulant proteins. Mechanism(s) leading to thrombosis, in addition to vessel injury, include one or all of the following: abnormal platelet adhesiveness-aggregation, an activated coagulation mechanism, a defective/deficient anticoagulant system, a dysfunctional fibrinolytic mechanism, and reduced blood flow. Arterial thrombosis appears to depend on vascular injury and platelet activation under high shear, whereas venous thrombosis generally occurs in low-flow (low-shear) conditions associated with activation of the coagulation mechanism or with an impaired inhibitor-fibrinolytic system.

The *clinical manifestations* reflect organ or tissue injury resulting from a severe reduction in blood perfusion or distention from occlusion of venous outflow. In general, vascular occlusive events in children have an acute or sudden onset. The diagnosis is made noninvasively by Doppler ultrasonography or MRI or by contrast angiography. Routine coagulation screening studies are rarely helpful in diagnosing a thromboembolic event. Studies in adults have suggested that quantitative assays of the D-dimer (formed when cross-linked fibrin is proteolysed by plasmin) are a sensitive screening tool for deep venous thrombosis (DVT) and especially for pulmonary emboli. In acute DIC, screening tests are strikingly abnormal, characterized by thrombocytopenia, hypofibrinogenemia, prolongation of the PT and PTT, and elevated D-dimers (see Chapter 475).

Acquired thrombotic and embolic events are uncommon in otherwise healthy children. Nevertheless, there are increasing reports of thromboembolism in newborns and in patients with specific diseases (Box 471–1). Arterial events usually present as stroke (at any age), a cold and pulseless lower extremity with or without renal involvement (aortic thrombosis in the newborn), and, rarely, myocardial infarction, although any organ can be affected. Venous events usually present as DVT with or without phlebitis, pulmonary embolism, and renal vein thrombosis.

The *lupus anticoagulant* causes a prolongation of the PTT that fails to correct on 1:1 mixing with normal plasma. The antibody is directed against the phospholipid used as a reagent in the PTT. The activated partial thromboplastin time (PTT or APTT) may be prolonged, but specific assays are needed to confirm the antiphospholipid antibody. Although the PTT is prolonged, the patient with an isolated lupus anticoagulant is not at increased risk of bleeding. Paradoxically, 5–20% of such individuals may develop arterial or venous thromboses. The lupus anticoagulant, either alone or as a component of the **antiphospholipid syndrome**, may be primary (idiopathic) or associated with systemic lupus erythematosus, infections, especially HIV, drug reactions, or other autoimmune diseases. Associated features include *livedo reticularis*, thrombocytopenia, recurrent fetal loss, and thrombosis (arterial or venous or both). Some children may develop an evanescent lupus anticoagulant after a viral illness. Treatment of thromboses includes warfarin with or without aspirin.

Venous Thrombosis and Thrombophlebitis.

Superficial thrombophlebitis is treated by anti-inflammatory drugs (nonsteroidal anti-inflammatory agents), heat compresses, rest, and elevation of the affected part. Patients with DVT or thrombophlebitis are treated with anticoagulation and sometimes with thrombolytic agents. Heparin anticoagulation should be used in a full dose for

Modified from Montgomery RR, Scott IP. Hemostasis: Diseases of the fluid phase. In Nathan DG, Oski FA (editors): Hematology of Infancy and Childhood, 4th ed. Vol 2. Philadelphia, WB Saunders, 1993.

3–5 days, with warfarin added for an additional 6 mo in those patients with proximal (above the knee) venous thrombosis. Patients with calf vein thrombosis may not require treatment. Experience with thrombolytic therapy in children is limited, but its efficacy is probably similar to that seen in adults. At this time, use of thrombolytic therapy should probably be limited to life- or limb-threatening situations.

Pulmonary Embolism.

The patient with acute pulmonary embolism (PE) can be treated with heparin or thrombolytic drugs. Thrombolytic therapy in adults produces a more rapid clinical improvement than heparin therapy, but the overall survival and long-term pulmonary function abnormalities appear to be the same in both treatment groups. Rarely, embolectomy is used when there is a large embolism and no benefit from thrombolytic or anticoagulant therapy.

Arterial Thrombosis.

Fibrinolytic therapy with either recombinant tPA (rTPA) or urokinase followed by heparin anticoagulation has been used successfully to treat acute arterial thromboses. Rarely, surgical removal of the clot is performed if lytic therapy is not successful or if the thrombosis affects a major organ or limb. Thrombolytic therapy cannot be employed if there has been recent surgery or central nervous system thrombosis/hemorrhage.

Stroke.

Arterial occlusion in the brain occurs when there is a vascular injury or anomaly or embolization from the heart; often these strokes are idiopathic. The most common cause of stroke in children is sickle cell disease. Venous thrombosis of cerebral vessels can be seen in those with cyanotic heart disease, inflammatory/infectious lesions of the brain or surrounding tissues, hyperviscosity states, or congenital thrombophilia. The therapeutic approach is directed toward the cause of the occlusion. Anticoagulation and/or platelet inhibitor drugs may be used. The presence of a hemorrhagic infarct is a contraindication to anticoagulant therapy. It is not known whether thrombolytic therapy is effective or safe in children with non-hemorrhagic strokes; but if used, it should only be used in patients with less than 3?hr of symptoms. Heparin therapy may improve the outcome of stroke in adults, although this is controversial.

471.1 Anticoagulant and Thrombolytic Therapy

Standard Unfractionated Heparin.

Heparin enhances the rate by which antithrombin III neutralizes the activities of several of the activated clotting proteins, especially factor Xa and thrombin. The average half-life of intravenously administered heparin is about 60?min in adults and can be as short as 30?min in the newborn. Heparin does not cross the placenta. The half-life of heparin is dose dependent; the higher the dose, the longer the circulating half-life. In thrombotic disease the half-life may be shorter than normal in patients with significant thromboembolism (e.g., pulmonary embolism) and longer than normal in patients with cirrhosis and uremia.

Anticoagulation with heparin is contraindicated in the following circumstances: a pre-existing coagulation defect or bleeding abnormality; a recent central nervous system hemorrhage; bleeding from inaccessible sites; malignant hypertension; bacterial endocarditis; recent surgery of the eye, brain, or spinal cord; and current administration of regional or lumbar block anesthesia. Despite these precautions, the frequency of bleeding in patients given heparin anticoagulation is 0.2–1%.

Heparin can be given as an intravenous or subcutaneous injection. It should not be given as an intramuscular injection. Although heparin can be administered by intermittent bolus injections of 75–100?U/kg every 4?hr, continuous administration is

associated with a lower risk of secondary hemorrhage. The current recommendation for continuous heparin is to give a bolus injection of 75?U/kg, followed by a continuous infusion of 28?U/kg/hr in infants younger than 1 yr of age or 20?U/kg/hr in children older than 1 yr. The goal is a PTT between 60 and 85?sec, which should correlate with a heparin level of 0.35–0.7 anti–factor Xa U/mL. If the PTT is less than 60?sec, increase the heparin dose rate by 10%. If it is less than 50?sec, re-administer a bolus of 50?U/kg and then increase the dose rate by 10%. If the PTT is more than 90?sec, stop the heparin dose for 30?min and then decrease the dose rate by 10%. If the dose must be adjusted, repeat the PTT in 4?hr. Once a stable therapeutic level has been reached, recheck the PTT daily. In newborns with low clotting factors, in patients with a lupus inhibitor, or in patients with elevated factor VIII (stress or surgery), the PTT may not

reflect the correct degree of anticoagulation, and specific heparin levels should be performed so that the heparin level is 0.35–0.70?U/mL by anti–factor Xa assay or 0.2–0.4?U/mL by protamine sulfate assay.

Heparin can be neutralized immediately by using protamine sulfate. Because of the rapid clearance rate of heparin, however, most patients can be treated by stopping the infusion. One milligram of protamine sulfate neutralizes between 90 and 110?U of heparin. Because heparin has a rapid in vivo metabolic decay, only half the total dose of protamine should be administered. A clotting test is performed to determine whether adequate neutralization has occurred; if not, the additional protamine can be given. Protamine itself is an anticoagulant; thus, if too much is given the clotting time may be prolonged. Although excess protamine has an anticoagulant effect, it rarely (if ever) is a cause of clinical bleeding. Once heparin is neutralized, the patient is returned to the original “prothrombotic” state.

LOW MOLECULAR WEIGHT HEPARIN.

Low molecular weight (LMW) heparin is an effective, convenient alternative to standard heparin therapy. Several heparins and heparinoids are undergoing clinical trials. The majority of the pediatric experience is with enoxaparin. Adult patients receiving LMW heparin rarely need to have heparin levels monitored, but in pediatric patients there is more diversity of response. Thus, monitoring should be performed to be sure that a therapeutic level is achieved. To treat a thrombus in older children, 1?mg/kg of enoxaparin every 12?hr subcutaneously is usually effective. In newborn and young infants, the dose is 1.6?mg/kg every 12?hr to achieve a therapeutic level. The PTT cannot be used to monitor LMW heparin; a specific assay for LMW heparin level should be used. The therapeutic level is more than 0.6?U/mL at 3?hr after injection. Prophylaxis is achieved with doses of 0.5?mg/kg every 12?hr subcutaneously. Prophylaxis levels demonstrate an anti-Xa assay of more than 0.3?U. Once a therapeutic range is achieved, routine monitoring is not required or required only infrequently.

Warfarin.

The coumarin derivatives are oral anticoagulant drugs that act by decreasing the functional levels of the vitamin K–dependent coagulation factors: II, VII, IX, and X. In addition, protein C and protein S (the vitamin K–dependent anticoagulants) are reduced. These drugs inhibit vitamin K–dependent carboxylation of the precursor coagulation proteins. Warfarin probably acts by competitively inhibiting vitamin K metabolism. After the administration of warfarin, the levels of factors II, VII, IX, and X decrease gradually, according to their respective plasma half-life. Because factor VII has the shortest half-life, its level is the first to decrease, followed by factors IX and X, and finally factor II. It generally takes 4–5 days to reduce levels of all four coagulation factors consistent with effective anticoagulation.

The prothrombin time (PT) is the clotting test used to assess warfarin anticoagulation. Current recommendations are based on the International Normalized Ratio (INR), which permits comparison of PTs using a wide variety of reagents or instrument. The INR for standard treatment of thrombosis is 2.0–3.0. For mechanical heart valves, treatment of homozygous protein C deficiency, and DVT associated with the lupus anticoagulant, the INR should be between 3.0–4.0.

The starting dose of warfarin in children is 0.2?mg/kg/24?hr orally. After 48?hr the dose is adjusted based on the INR. If the INR is 1.1–1.4, increase the dose by 20%; if it is 1.5–1.9, increase by 10%. If the INR is 3.2–3.5, decrease the dose by 20%. If the INR is more than 3.5, hold the dose until the INR is less than 3.5, then restart at 20% less than the previous dose. If the INR is 2.0–3.0, continue the same dose.

The most serious side effect of warfarin is hemorrhage. This is often related to changes in the dose or metabolism of the drug. The addition or removal of certain drugs in the patient's therapeutic regimen can have significant effects on oral anticoagulation. For example, warfarin's effect can be enhanced by the administration of antibiotics, salicylates, anabolic steroids, chloral hydrate, laxatives, allopurinol, vitamin E, and methylphenidate HCl; its effect can be diminished by barbiturates, vitamin K, oral contraceptives, phenytoin, and others. Warfarin-induced bleeding is treated by discontinuation of the drug and the oral administration of vitamin K. Generally, the amount of vitamin K given is equal to the amount of the daily warfarin dose. Vitamin K can be administered orally, subcutaneously, or intravenously (not intramuscularly) but the parenteral forms have a much longer half-life and may overshoot the correction. Correction of the coagulopathy begins within 6–8?hr and should be complete in 24–48?hr. If the patient is having a significant or life-threatening hemorrhage, fresh frozen plasma (15?mL/kg) should be given at the same time as the vitamin K is administered.

Coumarin anticoagulants are contraindicated in essentially the same circumstances as those for heparin therapy. The oral anticoagulants are teratogenic, cross the placenta, and should not be given during pregnancy—particularly during the first trimester. Although breast milk contains warfarin, the quantity is insignificant and the drug can be used to treat the lactating mother.

Thrombolytic Therapy.

Thrombolytic agents such as streptokinase, urokinase, and tissue-type plasminogen activator (rTPA) activate plasminogen to lyse blood clots by enzymatic digestion. Urokinase and rTPA act as direct activators, whereas streptokinase acts by binding to plasminogen, and the streptokinase-plasminogen complex becomes the plasminogen activator. For this therapy to be effective, the patient should have a

relatively fresh clot (<3–5 days old), the clot must be accessible to the lytic agent, and there must be an adequate amount of plasminogen. Once plasmin has been formed, it lyses fibrin. The plasmin generated by urokinase and streptokinase can produce a systemic hyperfibrinolytic state; when this occurs, the plasmin can degrade other plasma proteins, including fibrinogen, and factors V and VIII, resulting in a hemorrhagic disorder. rTPA is relatively more fibrin specific than urokinase; it serves as an activator within or on a fibrin clot. Clinical trials with rTPA suggest that a systemic hyperfibrinolytic state is rarely produced. The initial dose of rTPA is 0.1?mg/kg/hr with therapeutic effect determined by an increase in concentration of d-dimers or fibrin degradation products (FDP). With urokinase, a loading dose of 4400?U/kg is administered and then followed by 4400?U/kg/hr with therapeutic effectiveness monitored by a moderate drop in fibrinogen and the presence of detectable d-dimers. Higher doses or more prolonged courses of thrombolytic therapy are likely associated with an increased risk of bleeding complications.

Thrombolytic therapy has been reported to be beneficial in those with pulmonary embolism, DVT, certain arterial occlusive events, and occluded vascular access catheters. However, there are no controlled trials on its use in the pediatric group.

Chapter 472 - Postneonatal Vitamin K Deficiency

Although “late” hemorrhagic disease has been reported in breast-fed children, vitamin K deficiency occurring after the neonatal period is usually secondary to a lack of oral intake of vitamin K, alterations in the gut flora due to the long-term use of broad-spectrum antibiotics, or malabsorption of vitamin K (see also Chapter 92). Intestinal malabsorption of fats may accompany cystic fibrosis or biliary atresia and result in a deficiency of fat-soluble, dietary vitamin K with a reduced synthesis of the vitamin K–dependent clotting factors (factors II, VII, IX, X, protein C, and protein S). Prophylactic administration of water-soluble vitamin K orally is indicated in these cholestatic situations (2–3?mg/24?hr for children and 5–10?mg/24?hr for adolescents and adults) or vitamin K, 1–2?mg, may be administered intravenously. In patients with advanced cirrhosis, synthesis of many of the clotting factors may be reduced because of hepatocellular damage. In these patients, vitamin K may be ineffective. The anticoagulant properties of warfarin (Coumadin) and related anticoagulants depend on interference with vitamin K with a concomitant reduction of factors II, VII, IX, and X. Rat poison (superwarfarin) produces a similar deficiency; vitamin K is a specific antidote.

Chapter 473 - Liver Disease

Since all the clotting factors are produced exclusively in the liver except factor VIII, coagulation abnormalities are very common in patients with severe liver disease. Only 15% of such patients, however, have significant clinical bleeding states. The severity of the coagulation abnormality appears to be directly proportional to the extent of hepatocellular damage. The most common mechanism causing the defect is decreased synthesis of the coagulation factors. Severe liver disease characteristically has normal to increased (not reduced) levels of factor VIII activity in plasma. In some instances, disseminated intravascular coagulation (DIC) or hyperfibrinolysis may complicate liver diseases, making the laboratory differentiation of severe liver disease from DIC difficult.

The treatment of the coagulopathy of liver disease consists of replacement with fresh frozen plasma (FFP) or cryoprecipitate. FFP (10–15?mL/kg) contains all clotting factors, but replacement of fibrinogen may require cryoprecipitate. For severe hypofibrinogenemia, cryoprecipitate is recommended to replace fibrinogen at a dose of 1 bag/5?kg body weight. Because a reduction in the vitamin K-dependent coagulation factors is common in those with acute and chronic liver disease, vitamin K therapy can be given as a trial. The vitamin K can be given orally, subcutaneously, or intravenously (not intramuscularly) in a dose of 1?mg/24?hr for infants, 2–3?mg for children, and 5–10?mg for adolescents and adults. An inability to correct the coagulopathy indicates that the coagulopathy may be caused by a reduction in one or more of the non-vitamin K dependent proteins or because the liver is severely impaired and cannot produce the precursor vitamin K proteins.

Frequently, severe liver disease is associated with moderate prolongation of the bleeding time that is not corrected by either vitamin K or plasma replacement. DDAVP (0.3?µg/kg IV) has been found to be effective in shortening the bleeding time and has been used effectively to augment hemostasis prior to liver biopsy.

Chapter 474 - Acquired Inhibitors of Coagulation

Acquired circulating anticoagulants (inhibitors) are antibodies that react or cross react with clotting proteins and cause screening tests such as the partial thromboplastin time and prothrombin time to be prolonged. Many of these anticoagulants are autoantibodies that react with phospholipid and thereby interfere with clotting in vitro but not in vivo. These antibodies have been referred to as the lupus anticoagulant (see also Chapter 471). These circulating anticoagulants are uncommon in otherwise normal children. They are found in patients with systemic lupus erythematosus (SLE) or lymphomas or in those with penicillin or other drug reactions. They are a subset of antibodies found as a component of the *antiphospholipid syndrome*. Spontaneous inhibitors have been reported in children after incidental viral infections. Paradoxically, the lupus anticoagulant is rarely associated with bleeding symptoms but is associated with a predisposition to thrombosis. The mechanism(s) for the prothrombotic tendency associated with the lupus anticoagulant is likely multifactorial as these antibodies are heterogeneous in character.

Clinical Manifestations.

Bleeding symptoms in a patient with the lupus anticoagulant may be caused by thrombocytopenia, as a manifestation of the antiphospholipid syndrome or lupus itself, or rarely by a specific autoantibody against prothrombin (factor II). This antibody does not inactivate prothrombin but causes accelerated clearance of prothrombin, resulting in low levels of prothrombin.

Rarely, antibodies may arise spontaneously against a specific clotting factor, such as factor VIII or von Willebrand factor, similar to those seen more frequently in elderly patients. These patients are prone to excessive hemorrhage and may require specific treatment. In patients with a hereditary deficiency of a clotting factor (factor VIII or factor IX), antibodies may develop after exposure to transfused factor concentrates. These hemophilic inhibitory antibodies are discussed in Chapter 468 .

Laboratory Findings.

Inhibitors against specific coagulation factors usually affect factors VIII, IX, and XI or, rarely, prothrombin. The PTT or the PT may be prolonged and is not corrected in vitro with the addition of normal plasma, unless the antibody is a noninhibitory antibody that promotes rapid clearance of the protein. Specific factor assays determine which factor is involved.

The most common inhibitor is the "lupus anticoagulant" that is found in patients with

SLE, other collagen-vascular diseases, or sometimes after common viral infections, including HIV. The lupus anticoagulant produces a prolonged PTT and, if severe, a prolonged PT. The addition of normal, platelet-poor plasma in a 1:1 ratio with the test plasma does not correct the abnormal tests, but the addition of platelets neutralizes the anticoagulant.

More specific assays are necessary to confirm the presence of the lupus anticoagulant.

Treatment.

Management of the patient with an inhibitor against a specific coagulation factor is the same as for the hemophilia patient who develops an alloantibody against factor VIII or IX. Infusions of a prothrombin complex concentrate, activated prothrombin complex concentrate (FEIBA or Autoplex), porcine factor VIII, or recombinant factor VIIa concentrate may be needed to control significant bleeding. Spontaneous inhibitors that arise after a viral infection tend to disappear within a few weeks to months. Inhibitors seen with an underlying disease often disappear when the primary disease is treated. The lupus anticoagulant will often disappear after appropriate treatment of SLE. Thrombotic complications of the lupus anticoagulant should be treated with anticoagulants similar to other thrombotic events. Monitoring anticoagulant treatment may be complicated by the lupus anticoagulant and may require specific assays such as a heparin assay rather than the PTT or a factor X level rather than a PT. Maintenance of an International Normalized Ratio of 3–4, higher than for other patients with deep venous thrombosis, is recommended when thrombosis occurs with lupus inhibitors.

Chapter 475 - Disseminated Intravascular Coagulation (Consumptive Coagulopathy)

Consumption coagulopathy refers to a heterogeneous group of conditions, including disseminated intravascular coagulation (DIC), that result in consumption of clotting factors, platelets, and anticoagulant proteins. Consequences of this process include widespread intravascular deposition of fibrin leading to tissue ischemia and necrosis, a generalized hemorrhagic state, and hemolytic anemia.

Etiology.

A number of life-threatening pathologic processes, including hypoxia, acidosis, tissue necrosis, shock, and endothelial damage, may trigger DIC. Accordingly, it is not surprising that a large number of conditions have been reported to be associated with DIC, including septic shock (especially meningococcemia), incompatible blood transfusions, rickettsial infections, snakebite, purpura fulminans, giant hemangioma, and malignancies, especially acute promyelocytic leukemia. Although the clinical symptoms are primarily hemorrhagic, the initiating event is usually excessive activation of clotting that consumes both the physiologic anticoagulants (protein C, protein S, antithrombin III) and procoagulants, resulting in a deficiency of factor VIII, factor V, prothrombin, fibrinogen, and platelets. Commonly, the clinical result of this sequence of events is hemorrhage. The hemostatic dysregulation may also result in thrombotic susceptibility in the skin, kidneys, and other organs.

Clinical Manifestations.

Most frequently, DIC accompanies a severe systemic disease process. Bleeding frequently first occurs from sites of venipuncture or surgical incision. The skin may show petechiae and ecchymoses. Tissue necrosis may involve many organs and can be most spectacularly seen as infarction of large areas of skin, subcutaneous tissue, or kidneys. Anemia caused by hemolysis may develop rapidly owing to microangiopathic hemolytic anemia.

Laboratory Findings.

There is no well-defined sequence of events. Certain coagulation factors (II, V, VIII, and fibrinogen) and platelets may be consumed by the ongoing intravascular clotting process, with resultant prolongation of the prothrombin, partial thromboplastin, and thrombin times. Platelet counts may be profoundly depressed. The blood smear may contain fragmented, burr, and helmet-shaped red blood cells (schistocytes). In addition, because the fibrinolytic mechanism is activated, fibrinogen degradation products (FDPs, d-dimers) appear in the blood. The d-dimer is formed by fibrinolysis of a cross-linked fibrin clot. The d-dimer assay is equally sensitive and more specific for activation of coagulation and fibrinolysis than the FDP test.

Treatment.

The first two steps in the treatment of DIC are the critical ones: (1) treat the trigger that caused the DIC and (2) restore normal homeostasis by correcting the shock, acidosis, and hypoxia that usually complicate the DIC. If the underlying problem can be controlled, bleeding quickly ceases, and there is improvement of the abnormal laboratory findings. Blood components are used for replacement therapy in patients who have hemorrhage. This may consist of platelet infusions (for thrombocytopenia), cryoprecipitate (for hypofibrinogenemia), and/or fresh frozen plasma (for replacement of other coagulation factors and natural inhibitors).

In DIC associated with sepsis, a recent controlled trial of activated protein C (APC) in adults with sepsis demonstrated a statistically significant survival advantage for those treated with APC. Studies of APC in purpura fulminans in adults and children also suggest that APC helps reverse or ameliorate the process.

Heparin has been found occasionally to be effective in children with DIC associated with purpura fulminans and acute promyelocytic leukemia. Continuous heparin at a dose of 5–10?U/kg/hr without a loading dose may be used for those with acute promyelocytic leukemia. Heparin is not indicated and has been reported to be ineffective in septic shock, snake envenomation, heat stroke, massive head injury, and incompatible blood transfusion reaction, unless there is clear evidence of vascular thrombosis. Patients who develop vascular thrombosis due to DIC should be treated as outlined in Chapter 471.1 with careful attention to replacement therapy to maintain an adequate platelet count. Some individuals with DIC appear to have incipient ischemia with poorly perfused extremities. When this occurs, the DIC may be treated with heparin to prevent ongoing consumption of factors and progression of thromboses. Because administering heparin to patients with a deficiency of both clotting factors and platelets may result in profound hemorrhage, the heparin is usually started together with clotting factor and platelet replacement. Heparin is usually administered continuously, starting with a low dose of 5–10?U/kg/hr. The duration and effectiveness of heparin therapy can be judged by serial measurements of the platelet count, fibrinogen level, and d-dimer assay.

Chapter 476 - Platelet and Blood Vessel Disorders

Megakaryopoiesis.

Platelets are non-nucleated cellular fragments produced by megakaryocytes within the bone marrow and other tissues. Megakaryocytes are large polyploid cells. When the megakaryocyte approaches maturity, budding of the cytoplasm occurs and large numbers of platelets are liberated. Platelets circulate with a life span of 10 to 14 days. Thrombopoietin (TPO) is the major hormone that controls platelet production. Levels of TPO appear to correlate inversely with platelet number and with megakaryocyte mass. Thus, levels of TPO are highest in thrombocytopenic states associated with decreased marrow megakaryopoiesis and may be variable in states of increased platelet production.

The platelet plays multiple hemostatic roles. The platelet surface possesses a number of important receptors for adhesive proteins, including von Willebrand factor (VWF) and fibrinogen as well as receptors for agonists that trigger platelet aggregation, such as thrombin, collagen, and adenosine diphosphate (ADP). After injury to the blood vessel wall, subendothelial collagen binds VWF. VWF undergoes a conformational change that induces binding of the platelet glycoprotein Ib complex (the VWF receptor). This process is called platelet adhesion. Platelets then undergo activation. During the process of activation, the platelets generate thromboxane A_2 from arachidonic acid via the enzyme cyclooxygenase. After activation they release agonists such as ADP, adenosine triphosphate (ATP), Ca^{2+} , serotonin, and coagulation factors into the surrounding milieu. Circulating fibrinogen binds to its receptor on the activated platelets, the GPIIb-IIIa complex, linking platelets together in a process called aggregation. This series of events forms a hemostatic plug at the site of vascular injury. The serotonin and histamine liberated during activation increase local vasoconstriction. In addition to acting in concert with the vessel wall to form the platelet plug, the platelet provides the catalytic surface on which coagulation factors assemble and eventually generate thrombin through a sequential series of enzymatic cleavages. Last, the platelet contractile apparatus mediates clot retraction.

Thrombocytopenia.

The normal platelet count is 150 to 450 × 10^9 /L. Thrombocytopenia refers to a reduction in platelet count below 150 × 10^9 /L. Causes of thrombocytopenia include (1) decreased production on either a congenital or an acquired basis, (2)

sequestration of the platelets within an enlarged spleen or other organ, and (3) increased destruction of normally synthesized platelets either on an immune or a nonimmune basis. See also Chapters 460 , 461 , and 475 .

476.1 Idiopathic Thrombocytopenic Purpura

The most common cause for acute onset of thrombocytopenia in an otherwise well child is (autoimmune) idiopathic thrombocytopenic purpura (ITP).

Etiology.

One to 4 wk after exposure to a common viral infection, a small number of children develop an autoantibody directed against the platelet surface. The exact antigenic target for most such antibodies in acute ITP remains undetermined. After binding of the antibody to the platelet surface, circulating antibody-coated platelets are recognized by the Fc receptor on the splenic macrophages, ingested, and destroyed. A preceding history of a viral illness is described in 50–65% of cases of childhood ITP. The reason why some children respond to a common infection with an autoimmune disease remains unknown. Virtually every common infectious virus has been described in association with ITP, including Epstein-Barr (EBV) and HIV. EBV-related ITP is usually of short duration and follows the course of infectious mononucleosis. HIV-associated ITP is usually chronic.

Clinical Manifestations.

The classic presentation of ITP is that of a previously healthy 1–4 yr old child who has the sudden onset of generalized petechiae and purpura. The parents often state that the child was fine yesterday and now is covered with bruises and purple dots. Often there is bleeding from the gums and mucous membrane, particularly with profound thrombocytopenia (platelet count $< 10 \times 10^9$ /L). There is a history of a preceding viral infection 1 to 4 wk before onset of the thrombocytopenia. The physical examination is normal other than the finding of petechiae and purpura. Splenomegaly is rare. The presence of abnormal findings such as hepatosplenomegaly or remarkable lymphadenopathy suggests other diagnoses. When the onset is insidious, especially in an adolescent, the possibility of chronic ITP or that thrombocytopenia is a manifestation of a systemic illness such as systemic lupus erythematosus (SLE) is more likely.

In 70–80% of children who present with acute ITP, spontaneous resolution of their ITP will occur within 6 mo. Therapy does not appear to affect the natural history of the illness. Less than 1% of cases develop intracranial hemorrhage. Nevertheless, the objective of early therapy is to raise the platelet count to more than 20×10^9 /L and prevent the rare development of intracranial hemorrhage. Ten to 20 percent of children who present with acute ITP go on to develop chronic ITP.

Laboratory Findings.

Severe thrombocytopenia (platelet count $< 20 \times 10^9$ /L) is common, and platelet size is normal or increased, reflective of increased platelet turnover. In acute ITP, the hemoglobin value, white blood cell (WBC) count, and differential count should be normal. The hemoglobin may be decreased if there have been profuse nosebleeds or menorrhagia. The bone marrow examination, when done, reveals normal granulocytic and erythrocytic series with characteristically normal or increased numbers of megakaryocytes. Some of the megakaryocytes may appear to be immature and are reflective of increased platelet turnover. Indications for a bone marrow aspiration include an abnormal WBC count or differential or unexplained anemia as well as findings suggestive of bone marrow disease on history and physical examination. Other laboratory tests should be done as indicated by history and physical examination. An antinuclear antibody (ANA) test is more often positive in adolescents with ITP than in younger children and may indicate a higher likelihood of eventual chronic ITP. HIV studies should be done in at-risk populations, especially sexually active teens. Platelet antibody testing is seldom useful in acute ITP. A Coombs test should be done if there is unexplained anemia to rule out Evans syndrome (autoimmune hemolytic anemia and thrombocytopenia).

Differential Diagnosis.

The well-appearing child with moderate to severe thrombocytopenia and otherwise normal complete blood cell count (CBC) has a limited differential diagnosis that includes exposure to medication that induces drug-dependent antibodies, splenic sequestration due to previously unappreciated portal hypertension, and, rarely, early aplastic processes such as Fanconi anemia. Other than congenital syndromes such as amegakaryocytic thrombocytopenia and thrombocytopenia–absent radius syndrome, most marrow processes that interfere with platelet production will also cause abnormal synthesis of red blood cells and leukocytes and therefore will manifest abnormalities in the CBC. Disorders that cause increased platelet destruction on a nonimmune basis are usually serious

---

systemic illnesses with obvious clinical findings (hemolytic-uremic syndrome, disseminated intravascular coagulation). Isolated enlargement of the spleen suggests the potential for hypersplenism owing to either liver disease or portal vein thrombosis. Autoimmune thrombocytopenia may be an initial manifestation of SLE, HIV infection, or rarely, lymphoma. Wiskott-Aldrich syndrome must be considered in young males found to have low platelet counts, particularly if there is a history of eczema and recurrent infections.

Treatment.

There are no data that treatment affects either short-or long-term clinical outcome of ITP. When compared with untreated controls, treatment appears to be capable of inducing a more rapid rise in platelet count to the theoretically safe level of more than 20×10^9 /L. Antiplatelet antibodies will bind to transfused platelets as well as they do to autologous platelets. Thus, platelet transfusion in ITP is usually contraindicted unless life-threatening bleeding is present. Initial treatment options for ITP include the following:

1. *Intravenous immunoglobulin* (IVIG). IVIG in a dose of 0.8–1?g/kg/day × 1–2 days, induces a rapid rise in platelet count (usually $>20 \times 10^9$ /L) in 95% of

patients within 48?hr. IVIG therapy is both expensive and time-consuming to administer. Additionally, there is a high frequency of headaches and vomiting suggestive of aseptic meningitis after IVIG infusions.

2. *Prednisone*. Corticosteroid therapy has been used for many years to treat acute and chronic ITP in adults and children. Doses of 1–4?mg/kg/24?hr of prednisone appear to induce a more rapid rise in platelet counts than in untreated patients with ITP. Whether a bone marrow examination should be performed to rule out other causes for thrombocytopenia, especially acute lymphoblastic leukemia, before institution of prednisone therapy in acute ITP is controversial. Corticosteroid therapy is usually continued for 2–3 wk or until a rise in platelet count above 20,000 has been achieved with a rapid taper to avoid the long-term side effects of corticosteroid therapy, especially growth failure, diabetes mellitus, and osteoporosis.
3. *IV Anti- D Therapy*. The role of IV anti-D in initial therapy of acute ITP is under investigation. When given to Rh-positive individuals, IV anti-D induces a mild hemolytic anemia. RBC-antibody complexes bind to macrophage Fc receptors and interfere with platelet destruction, thereby causing a rise in platelet count. This increase appears to be somewhat slower than after IVIG. Whether this is a biologically relevant delay remains unclear, because 80–85% of patients receiving anti-D in a dose of 50?µg/kg have demonstrated a rise in platelet count to levels above 20×10^9 /L within 2 days.

Each of these medications may be used to treat exacerbations of ITP, which commonly occur several weeks after an initial course of therapy.

At the present time, there is no consensus regarding the management of acute ITP. Treatment guidelines have been published by the American Society of Hematology for adults with ITP, but there is significant disagreement within the field. Intracranial hemorrhage remains rare, and there are no data that treatment actually reduces the incidence of intracranial hemorrhage in ITP because of the rarity of the event.

The role of splenectomy in ITP should be reserved for one of two circumstances. The older child (=4 yr) with severe ITP that has lasted longer than 1 yr (chronic ITP) and whose symptoms are not easily controlled with therapy is a candidate for splenectomy. Splenectomy must also be considered when life-threatening hemorrhage (intracranial hemorrhage) complicates acute ITP if the platelet count cannot rapidly be corrected with transfusion of platelets and administration of IVIG and corticosteroids. Splenectomy is associated with a lifelong risk of overwhelming post-splenectomy infection caused by encapsulated organisms.

Chronic ITP.

Those 10–20% of patients who present with acute ITP and who have persistent thrombocytopenia for more than 6 mo have chronic ITP. At that time a careful re-evaluation for associated disorders should be performed, especially for autoimmune disease such as SLE and chronic infectious disorders such as HIV as well as nonimmune causes of chronic thrombocytopenia such as type 2B von Willebrand disease, X-linked thrombocytopenia, and Wiskott-Aldrich syndrome. Therapy should be aimed at controlling symptoms and preventing serious bleeding. In ITP the spleen is the primary site of antiplatelet antibody synthesis as well as the primary site of platelet destruction. Splenectomy is successful in inducing a complete remission in 64–88% of children with chronic ITP. This must be balanced against the lifelong risk of overwhelming post-splenectomy infection. This decision is often affected by lifestyle issues as well as the ease with which the child can be managed using medical therapy such as IVIG, corticosteroids, or IV anti-D. Before splenectomy the child should receive pneumococcal vaccine, and after splenectomy he or she should receive penicillin prophylaxis for a number of years. Whether penicillin prophylaxis should be lifelong is controversial.

476.2 Drug-Induced Thrombocytopenia

A number of drugs are associated with immune thrombocytopenia as the result of either an immune process or a megakaryocyte injury. Some common drugs used in pediatrics that cause thrombocytopenia include valproic acid, phenytoin, sulfonamides, and trimethoprim-sulfamethoxazole. Heparin-induced thrombocytopenia (and rarely thrombosis) is seldom seen in pediatrics but occurs when, after exposure to heparin, the patient develops an antibody directed against the heparin/ platelet factor IV complex.

476.3 Nonimmune Platelet Destruction

The syndromes of DIC, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura share the hematologic picture of a *thrombotic microangiopathy* in which there is red cell destruction and a consumptive thrombocytopenia caused by platelet and fibrin deposition in the microvasculature. The microangiopathic hemolytic anemia is characterized by the presence of RBC fragments, including helmet cells, schistocytes, spherocytes, and burr cells.

476.4 Hemolytic-Uremic Syndrome (HUS) (see also Chapter 510)

This acute disease of infancy and early childhood usually follows an episode of acute gastroenteritis, often triggered by *Escherichia coli* 0157:H7. Shortly thereafter, signs and symptoms of hemolytic anemia, thrombocytopenia, and acute renal failure ensue. Sometimes neurologic symptoms are associated with these findings. *E. coli* 0157:H7 produces a specific toxin (verotoxin) that binds to and damages renal endothelial cells preferentially.

The hemolytic anemia is characterized by abnormal red cell morphology with the presence of helmet cells, spherocytes, schistocytes, burr cells, and other distorted forms. Thrombocytopenia despite normal numbers of megakaryocytes in the marrow indicates excessive platelet destruction. Tests for DIC are usually normal except for elevated fibrin(ogen) degradation products. Evaluation of the urine shows the presence of protein, red blood cells, and casts. The presence of anuria and severe azotemia indicates grave renal damage. Treatment of most cases

of hemolytic-uremic syndrome involves institution of careful fluid management and prompt appropriate dialysis. Treatment using plasmapheresis is usually reserved for patients with hemolytic-uremic syndrome associated with major neurologic complications.

476.5 Thrombotic Thrombocytopenic Purpura (TTP)

This rare pentad of fever, microangiopathic hemolytic anemia, thrombocytopenia, abnormal renal function, and CNS changes is clinically similar to hemolytic-uremic syndrome, although TTP usually presents in adults and occasionally in adolescents. Microvascular thrombi within the central nervous system cause subtle, shifting neurologic signs that vary from changes in affect and orientation to aphasia, blindness, and convulsions. Prompt recognition of this disorder is critical. Laboratory findings demonstrate a microangiopathic hemolytic anemia characterized by abnormal red cell morphology with schistocytes, spherocytes, helmet cells, and an elevated reticulocyte count in association with thrombocytopenia. Coagulation studies are usually nondiagnostic. The treatment of TTP is plasmapheresis (plasma exchange), which is effective in 80–95% of cases. Corticosteroids and splenectomy are reserved for refractory cases.

The majority of cases of TTP are caused by an acquired deficiency of a metalloproteinase responsible for cleaving the high molecular weight multimers of VWF, which appear to play a pivotal role in the evolution of the thrombotic microangiopathy. In contrast, levels of the metalloproteinase in HUS are usually normal. A congenital deficiency of the metalloproteinase causes rare familial cases of TTP.

476.6 Kasabach-Merritt Syndrome (see also Chapter 640)

The association of a giant hemangioma with localized intravascular coagulation causing thrombocytopenia and hypofibrinogenemia is called the Kasabach-Merritt syndrome. In most patients the site of the hemangioma is obvious, but retroperitoneal and intra-abdominal hemangiomas may require body imaging for detection. Inside the hemangioma there is platelet trapping and activation of coagulation with fibrinogen consumption and generation of fibrin(ogen) degradation products. Arteriovenous malformation within the lesions can cause heart failure. Some authors contend that Kasabach-Merritt syndrome is really a kaposiform hemangioendothelioma rather than a simple hemangioma. The peripheral blood smear shows microangiopathic changes. Multiple modalities have been used to treat Kasabach-Merritt syndrome, including surgical excision (if possible), laser photocoagulation, corticosteroids in high doses, local x-ray therapy, and antiangiogenic agents such as interferon a_2 . Over time most patients who present in infancy have regression of the hemangioma. Treatment of the associated coagulopathy may benefit from a trial of antifibrinolytic therapy with e-aminocaproic acid (Amicar).

476.7 Sequestration

Individuals with massive splenomegaly develop thrombocytopenia, since the spleen acts as a sponge for platelets and sequesters large numbers. Most such patients will also have mild leukopenia and anemia on the CBC. Individuals who have thrombocytopenia caused by splenic sequestration should undergo a work-up to diagnose the etiology of splenomegaly, including infectious, infiltrative, neoplastic, obstructive, and hemolytic causes.

476.8 Congenital Thrombocytopenic Syndromes

Congenital amegakaryocytic thrombocytopenia is caused by a rare defect in hematopoiesis that usually manifests within the first few days to weeks of life, when the child presents with petechiae and purpura caused by profound thrombocytopenia. Other than skin and mucous membrane findings, the physical examination is normal. Examination of the bone marrow shows an absence of megakaryocytes. These patients often progress to marrow failure (aplasia) over time. Bone marrow transplantation is curative.

Thrombocytopenia–absent radius (TAR) syndrome consists of thrombocytopenia that presents in early infancy with radial anomalies of variable severity from mild changes to marked limb shortening. In many such individuals there are also other skeletal abnormalities of the lower extremities. Intolerance to formula may complicate management by triggering gastrointestinal bleeding. The thrombocytopenia of TAR syndrome frequently remits over the first few years of life. The molecular basis for amegakaryocytic thrombocytopenia and TAR syndrome is undefined at present.

The *Wiskott-Aldrich syndrome (WAS)* is characterized by thrombocytopenia with tiny platelets, eczema, and recurrent infections due to immune deficiency (see Chapter 116.11). WAS is inherited as an X-linked disorder, and the gene for WAS has been sequenced. The WAS protein appears to play an integral role in regulating the cytoskeletal architecture of both platelets and T lymphocytes in response to receptor-mediated cell signaling. The WAS protein is common to all cells of hematopoietic lineage. Molecular analysis of families with *X-linked thrombocytopenia* has shown that many members have a point mutation within the WAS gene, whereas individuals with the full manifestation of WAS have large gene deletions. Examination of the bone marrow in WAS shows the normal number of megakaryocytes, although the megakaryocytes may have bizarre morphology. Transfused platelets have a normal life span. Splenectomy often corrects the thrombocytopenia, suggesting that the platelets formed in WAS have accelerated destruction. After splenectomy, these patients are at increased risk of overwhelming infection and require lifelong antibiotic prophylaxis against encapsulated organisms. About 5% of WAS patients develop lymphoreticular malignancies. Successful bone marrow transplantation cures WAS.

476.9 Neonatal Thrombocytopenia (see also Chapter 92.4)

Thrombocytopenia in the newborn rarely is indicative of a primary disorder of megakaryopoiesis but more often is the result of either systemic illness or transfer of maternal antibodies directed against fetal platelets.

Thrombocytopenia may occur in various fetal and neonatal infections and be responsible for severe spontaneous bleeding. Neonatal thrombocytopenia often occurs in association with congenital viral infections, especially rubella and CMV; protozoal infections such as toxoplasmosis; syphilis; and bacterial infections, especially those caused by gram-negative bacilli. The constellation of marked thrombocytopenia and abnormal abdominal findings is common in necrotizing enterocolitis and other causes of necrotic bowel. The presence of thrombocytopenia

in an ill child requires a prompt search for viral and bacterial pathogens.

Antibody-mediated thrombocytopenia in the newborn occurs because of transplacental transfer of maternal antibodies directed against fetal platelets. **Neonatal alloimmune thrombocytopenic purpura (NATP)** is caused by the development of maternal antibodies against antigens present on fetal platelets that are shared with the father and recognized as foreign by the maternal immune system. This is the platelet equivalent of Rh

disease of the newborn (see Chapter 92.2). The incidence of NATP is 1 in 4,000–5,000 live births. The *clinical manifestations* of NATP are those of an apparently well child who, within the first few days after delivery, develops generalized petechiae and purpura. Laboratory studies show a normal maternal platelet count, yet moderate to severe thrombocytopenia in the newborn. Detailed historical review should show no evidence of maternal thrombocytopenia in the past. Up to 30% of infants with severe NATP may develop intracranial hemorrhage, either prenatally or in the perinatal period. Unlike Rh disease, first pregnancies may develop severe thrombocytopenia, and subsequent pregnancies may be more severely affected than the first.

The *diagnosis* of NATP is made by checking for the presence of maternal alloantibodies directed against the father's platelets. Specific studies can be done to identify the target alloantigen. The most common cause is incompatibility for $P1^{A1}$. Specific DNA sequence polymorphisms have been identified that permit informative prenatal testing to identify at-risk pregnancies. The differential diagnosis of NATP includes transplacental transfer of maternal antiplatelet autoantibodies (maternal ITP) and, more commonly, viral or bacterial infection.

Treatment for NATP is the administration of intravenous immunoglobulin (IVIG) prenatally to the mother. Therapy usually begins in the second trimester and is continued throughout the pregnancy. Fetal platelet counts can be monitored by percutaneous umbilical blood sampling (PUBS). Delivery should be performed by cesarean section. After delivery, if severe thrombocytopenia persists, transfusion of one unit of phenotypically matched platelets (washed maternal platelets) will cause a rise in platelet counts to provide effective hemostasis. After there has been one affected child, genetic counseling is critical to inform the parents of the high risk of thrombocytopenia in subsequent pregnancies.

Children born to mothers with ITP (maternal ITP) appear to have a lower risk of serious hemorrhage than infants born with NATP, although severe thrombocytopenia occurs. The mother's pre-existing platelet count may have some predictive value, in that severe maternal thrombocytopenia before delivery appears to predict a higher risk of fetal thrombocytopenia. Nevertheless, in mothers who have had splenectomy for ITP, the maternal platelet count may be normal and is not predictive of fetal thrombocytopenia.

Treatment includes prenatal administration of corticosteroids to the mother and administration of IVIG and sometimes corticosteroids to the infant after delivery. The thrombocytopenia in an infant, whether due to NATP or maternal ITP, usually resolves within 2 to 4 mo after delivery. The highest risk period remains in the immediate perinatal period.

476.10 Thrombocytopenia Due to Acquired Disorders Causing Decreased Production

Disorders of the bone marrow that inhibit megakaryopoiesis usually affect red cell and white cell production. Infiltrative disorders, including malignancies such as acute lymphocytic leukemia, histiocytosis, lymphomas, and storage disease, usually cause either abnormalities on physical examination (lymphadenopathy, hepatosplenomegaly, masses) or abnormalities of the WBC count, or anemia. Aplastic processes may present as isolated thrombocytopenia, although there are usually clues on the CBC (leukopenia, neutropenia, anemia, or macrocytosis). Children with constitutional aplastic anemia (Fanconi anemia) often have abnormalities on examination, including radial anomalies, other skeletal anomalies, short stature, microcephaly, and hyperpigmentation. A bone marrow examination should be done when thrombocytopenia is associated with abnormalities found on physical examination or on examination of the other blood cell lines.

476.11 Platelet Function Disorders

The bleeding time is the only commonly available test to screen for abnormal platelet function. The bleeding time measures indirectly the platelet count, platelet function, and interaction of platelets with the blood vessel wall. Unfortunately, the bleeding time is dependent on a number of other factors, including the skill of the technician and the cooperation of the patient. Therefore, its predictive value is often problematic. A normal bleeding time does not rule out a mild platelet function defect in a clinically symptomatic individual. The Platelet Function Analyzer (PFA) is being evaluated as a screening tool for platelet function disorders (see Chapter 467.2) and may supplant the bleeding time as a screening test in the future. Platelet function in the clinical laboratory is currently measured using platelet aggregometry. In the aggregometer, agonists such as collagen, ADP, ristocetin, arachidonic acid, and thrombin are added to platelet-rich plasma, and the clumping of platelets over time is measured by an automated machine. At the same time, other instruments measure the release of granular contents such as ATP from the platelets after activation. In this manner, the ability of platelets to aggregate and their metabolic activity can be assessed simultaneously. Mild disorders can frequently be managed with desmopressin (see hemophilia and von Willebrand disease treatment), but severe or life-threatening bleeding may require platelet transfusions. Because transfused platelets must compete with the patient's abnormal platelets, the clinical response to transfusion may be less than that seen with thrombocytopenia due to decreased production.

476.12 Acquired Disorders of Platelet Function

A number of systemic illnesses are associated with platelet dysfunction, most commonly liver disease, kidney disease (uremia), and those disorders that trigger increased amounts of fibrin degradation products. These disorders frequently cause a prolonged bleeding time and are often associated with other abnormalities of the coagulation mechanism. The most important element of management is to treat the

primary illness. If treatment of the primary process is not feasible, infusions of desmopressin have been helpful in augmenting hemostasis and correcting the bleeding time. In some patients, transfusions of platelets and/or cryoprecipitate have also been helpful in improving hemostasis.

Many drugs alter platelet function. The most commonly used drug in adults that alters platelet function is acetylsalicylic acid (aspirin). Aspirin irreversibly acetylates the enzyme cyclooxygenase, which is critical in the formation of thromboxane A_2 . Aspirin usually causes moderate platelet dysfunction, which becomes more prominent if there is some other abnormality of the hemostatic mechanism. Other commonly used drugs that affect platelet function include other nonsteroidal anti-inflammatory drugs, valproic acid, and high-dose penicillin. Therefore, when evaluating a patient for a possible platelet dysfunction, it is critically important to exclude the presence of other exogenous agents and to study the patient, if possible, off all medications for 2 wk.

476.13 Congenital Abnormalities of Platelet Function

Severe platelet function defects usually present with petechiae and purpura shortly after birth, especially after vaginal delivery. Defects in the VWF receptor, the glycoprotein Ib (GPIb) complex, or the fibrinogen receptor, the glycoprotein IIb-IIIa (GPIIb-IIIa) complex, cause severe congenital platelet dysfunction.

Bernard-Soulier syndrome, a congenital bleeding disorder, is characterized by thrombocytopenia with giant platelets and a markedly prolonged bleeding time (>20 minutes). Platelet aggregation tests show absent ristocetin-induced platelet aggregation but normal aggregation to all other agonists. Studies of VWF are normal. Ristocetin induces the binding of VWF to platelets. The cause for this severe platelet dysfunction is the absence or severe deficiency of the VWF receptor (GPIb complex) on the platelet membrane. This complex interacts with the platelet cytoskeleton; the defect in this interaction is thought to be the cause for the large platelet size. Bernard-Soulier syndrome is inherited as an autosomal recessive disorder.

Glanzmann thrombasthenia is a congenital disorder associated with severe platelet dysfunction that yields a prolonged bleeding time and a normal platelet count. The platelet morphology and size are normal on the peripheral blood smear. The bleeding time is markedly prolonged. Aggregation studies show abnormality of aggregation with all agonists used except ristocetin, because ristocetin agglutinates platelets and does not require a metabolically active platelet. This disorder is caused by deficiency of the platelet fibrinogen receptor, GPIIb-IIIa, an integrin complex on the platelet surface that undergoes conformational changes when platelets are activated. Fibrinogen binds to this complex and causes platelets to aggregate. This disorder is inherited in an autosomal recessive manner.

Hereditary deficiency of platelet storage granules occurs in two well-characterized but rare syndromes that involve deficiency of intracytoplasmic granules. **Dense body deficiency** is characterized by the absence of the granules that contain ADP, ATP, Ca^{2+} , and serotonin. This disorder is diagnosed by absent release of ATP on platelet aggregation studies and ideally characterized by electron microscopic studies. **Gray platelet syndrome** is caused by the absence of platelet a granules resulting in platelets that appear gray on Wright stain of peripheral blood. This rare syndrome has absent aggregation and release with most agonists other than thrombin and ristocetin. Electron microscopic studies are diagnostic.

Other Hereditary Disorders of Platelet Function.

Abnormalities in the pathways of platelet activation and release of granular contents cause a heterogeneous group of platelet function defects that are usually manifested as increased bruising, epistaxis, and/or menorrhagia. Symptoms may be subtle and are often made more obvious by high-risk surgery, such as tonsillectomy/adenoidectomy, or by administration of nonsteroidal anti-inflammatory drugs. In the laboratory, the bleeding time is variable, although it is frequently but not always prolonged. Platelet aggregation studies show deficient aggregation with one or two agonists and/or abnormal release of granular contents.

Formation of thromboxane from arachidonic acid after activation of phospholipase is critical to normal platelet function. Deficiency or dysfunction of enzymes such as cyclooxygenase and thromboxane synthase, which metabolize arachidonic acid, causes abnormal platelet function. In the aggregometer, platelets from such patients fail to aggregate in response to arachidonic acid.

The most common platelet function defects are those characterized by a variable bleeding time and abnormal aggregation with one or two agonists, usually ADP and/or collagen. These patients have normal aggregation with thrombin. Some of these individuals have only decreased release of ATP from intracytoplasmic granules. This selective release defect is a common cause of a mild platelet function defect.

Treatment of Platelet Function Defects.

Successful treatment depends on the severity of the diagnosis and of the hemorrhagic event. In all but the severe platelet function defects, desmopressin, 0.3?µg/kg IV, may be used for mild to moderate bleeding episodes. In addition to its effect on stimulating levels of VWF and factor VIII, desmopressin corrects the bleeding time and provides normal hemostasis in many individuals with mild to moderate platelet function defects. For individuals with Bernard-Soulier syndrome or Glanzmann thrombasthenia, platelet transfusions, 1 U/5–10?kg, will correct the defect in hemostasis and may be lifesaving. Both alloantibodies and anti-HLA antibodies that may develop after numerous platelet transfusions may limit the effectiveness of platelet transfusion therapy. In such patients, the use of recombinant factor VIIa has been effective and is undergoing clinical trials. In both conditions, stem cell transplants would be expected to be curative. Because the first hemostatic event involves the GPIb receptor, partial stem cell reconstitution may be successful in Bernard-Soulier syndrome patients because the normal platelets would be those that preferentially adhere.

476.14 Disorders of the Blood Vessels

Henoch-Schönlein Purpura (HSP).

This syndrome is characterized by the sudden development of a purpuric rash, arthritis, abdominal pain, and renal involvement (see Chapter 157.1). The characteristic rash, consisting of petechiae and often palpable purpura, usually involves the lower extremities and buttocks. Coagulation studies are normal. The pathologic lesions in the skin, intestines, and synovium are a *leukocytoclastic angiitis*—inflammatory damage to the endothelium of the capillary and postcapillary venules mediated by WBCs and macrophages. The trigger for HSP is unknown. In the kidney the lesion is focal glomerulonephritis with deposition of IgA. Coagulation studies and the platelet count are normal in HSP.

Ehlers-Danlos Syndrome.

This disorder of collagen structure causes easy bruising and poor wound healing (see Chapter 649). Suggestive findings on physical examination include soft, velvety skin that is hyperelastic and lax joints that are easily subluxed. More than 10 variants of Ehlers-Danlos syndrome have been described. The most serious forms have been associated with sudden rupture of visceral organs. Coagulation screening tests are usually normal, other than the bleeding time, which may be mildly prolonged. Platelet aggregation studies are either normal or mildly abnormal with deficient aggregation to collagen.

Acquired Disorders.

Scurvy, chronic corticosteroid therapy, and severe malnutrition are associated with “weakening” of the collagen matrix that supports the blood vessels and therefore are associated with easy bruising and, particularly in the case of scurvy, bleeding gums and loosening of the teeth. Lesions of the skin that initially look like petechiae and purpura may be seen in vasculitic syndromes such as SLE.

Chapter 477 - Anatomy and Function of the Spleen

Anatomy.

The splenic precursor is recognizable by the 5th wk of gestation. At birth, the spleen weighs approximately 11?g. Thereafter, it enlarges until puberty, reaching an average weight of 135?g before diminishing in size during adulthood. The major splenic components are a lymphoid compartment (white pulp) and a filtering system (red pulp). The white pulp consists of periarterial lymphatic sheaths of T cells with embedded germinal centers containing B cells. The red pulp has a skeleton of fixed reticular cells, mobile macrophages, partially collapsed endothelial passages (cords of Billroth), and splenic sinuses. A marginal zone rich in dendritic (antigen-presenting) cells separates the red pulp from the white. The splenic capsule contains smooth muscle and contracts in response to epinephrine. Approximately 10% of the blood delivered to the spleen flows rapidly through a closed vascular network. The other 90% flows more slowly through an open system (the splenic cords) where it is filtered through 1–5?µm slits before entering the splenic sinuses.

Function.

Unique anatomy and blood flow enable the spleen to perform reservoir, filtering, and immunologic functions more effectively. The spleen receives 5–6% of the cardiac output but normally contains only 25?mL of blood. It can retain much more when it enlarges. Hematopoiesis is a major splenic function from 3–6 mo of fetal life but then disappears. Splenic blood formation can be resumed in patients with myelofibrosis or severe hemolytic anemia. Factor VIII and platelets are stored in the spleen and can be released by stress or an epinephrine injection. Thrombocytosis and leukocytosis occur with loss of the splenic reservoir function. The high platelet counts do not appear to be associated with an increased risk of thrombosis in children.

Slow blood flow past macrophages and through small openings in the sinus walls facilitates the filtering functions of the spleen. Excess membrane is removed from young red blood cells (RBCs); loss of this function is characterized by target cells, poikilocytosis, and decreased osmotic fragility. The spleen is the primary site for destruction of old RBCs; this function is assumed by other reticuloendothelial cells after splenectomy. The spleen also removes damaged and abnormal cells such as spherocytes and antibody-coated RBCs. Intracytoplasmic inclusions may be removed from RBCs without cell lysis. Functional or anatomic hyposplenia is characterized by continued circulation of cells containing nuclear remnants (Howell-Jolly bodies), denatured hemoglobin (Heinz bodies), and other debris in the RBC. The latter may appear as “pits” on indirect microscopy. The spleen may be an important site of antibody production in immune thrombocytopenia.

Immunoglobulin, properdin, and tuftsin are produced in the spleen. The spleen has a minor role in antibody responses to intramuscularly or subcutaneously injected antigens but is required for early antibody production after exposure to intravenous antigens. Thus, young (nonimmune) or hyposplenic individuals are at increased risk for sepsis caused by pneumococci and other encapsulated bacteria. The spleen can also use phagocytosis to trap and destroy intracellular parasites. The spleen may be an important site of antibody production in immune thrombocytopenic purpura.

Chapter 478 - Splenomegaly

Clinical Manifestations.

A soft, thin spleen may be palpable in 15% of neonates, 10% of normal children, and 5% of adolescents. However, in most individuals, the spleen must be two to three times its normal size before it is palpable. The spleen is best examined in a supine patient by palpating across the abdomen toward the left costal margin from below as the patient inspires deeply. One should remember that an enlarged spleen may descend into the pelvis; thus, when splenomegaly is suspected, the abdominal examination should begin at a lower starting point. Superficial abdominal venous distention may be present when splenomegaly is a result of portal hypertension. Radiologic detection or confirmation of splenic enlargement is done with ultrasonography, CT, or a technetium-99m sulfur colloid scan. The latter also assesses splenic function.

Differential Diagnosis.

Specific causes of splenomegaly are listed in Box 478–1 . Unique problems are discussed next.

Pseudosplenomegaly.

Abnormally elongated mesenteric connections may produce a wandering or ptotic spleen. An enlarged left lobe of the liver, a left upper quadrant mass, or a splenic hematoma may be mistaken for splenomegaly. Splenic cysts may contribute to splenomegaly or mimic it; these may be congenital (epidermoid) or acquired (pseudocyst) after trauma or infarction. Cysts are usually asymptomatic and are found on radiologic evaluation. Splenosis after splenic rupture or an accessory spleen (present in 10% of normal individuals) may also mimic splenomegaly; most, however, are not palpable. The syndrome of *congenital polysplenism* includes cardiac defects, left-sided organ anomalies, bilobed lungs, biliary atresia, and pseudosplenomegaly (see Chapter 424.11)

Hypersplenism.

Hypersplenism is characterized by increased splenic function (sequestration or destruction of circulating cells), which results in peripheral blood cytopenias, increased bone marrow activity, and splenomegaly. It is usually secondary to another disease and may be cured by treatment of the underlying condition or, if absolutely necessary, moderated by splenectomy.

Congestive Splenomegaly (Banti's Syndrome).

Splenomegaly may result from obstruction in the hepatic, portal, or splenic veins. Wilson disease, galactosemia, biliary atresia, and a-antitrypsin deficiency result in hepatic inflammation, fibrosis, and vascular obstruction. Congenital abnormalities of the portal or splenic veins may cause vascular obstruction. Septic omphalitis or umbilical venous catheterization in neonates may also result in secondary obliteration of these vessels. Splenic venous flow may be obstructed by masses of sickled erythrocytes. When the spleen is the site of vascular obstruction, splenectomy cures hypersplenism. However, the obstruction usually is in the hepatic or portal systems, and portocaval shunting may be more helpful, because both portal hypertension and thrombocytopenia contribute to variceal bleeding.

Box 478-1. Common Causes of Splenomegaly

INFECTION

Bacterial: Typhoid fever, endocarditis, septicemia, abscess

Viral: Epstein-Barr, cytomegalovirus, and others

Protozoal: Malaria, toxoplasmosis

HEMATOLOGIC PROCESSES

Hemolytic anemia: Congenital, acquired

Extramedullary hematopoiesis: Thalassemia, osteopetrosis, myelofibrosis

NEOPLASMS

Malignant: Leukemia, lymphoma,

NEOPLASMS

Malignant: Leukemia, lymphoma, histiocytoses, metastatic tumors

Benign: Hemangioma, hamartoma

METABOLIC DISEASES

Lipidoses: Niemann-Pick, Gaucher diseases

Mucopolysaccharidosis infiltration: Histiocytosis

CONGESTION

Cirrhosis or hepatic fibrosis

Hepatic portal or splenic vein obstruction

Congestive heart failure

CYSTS

Congenital (true cysts)

Acquired (pseudocysts)

MISCELLANEOUS

Lupus erythematosus, sarcoidosis, rheumatoid arthritis

Chapter 479 - Hyposplenism, Splenic Trauma, and Splenectomy

Congenital absence of the spleen is associated with complex cyanotic heart defects, dextrocardia, bilateral trilobed lungs, and heterotopic abdominal organs (Ivemark's syndrome; see Chapter 424.11). Splenic function is usually normal in children with congenital polysplenia. *Functional hyposplenism* may occur in normal neonates, especially premature infants. Children with sickle cell hemoglobinopathies may develop splenic hypofunction as early as 6 mo of age. Initially, this is caused by vascular obstruction, which can be reversed with red blood cell (RBC) transfusions. The spleen eventually autoinfarcts, resulting in a fibrotic, permanently nonfunctioning spleen. Functional hyposplenism may also occur in malaria, after irradiation to the left upper quadrant, and when the reticuloendothelial function of the spleen is overwhelmed (as in severe hemolytic anemias or metabolic storage diseases). Splenic hypofunction has been reported occasionally in patients with vasculitides, nephritis, inflammatory bowel disease, coeliac disease, Pearson syndrome, Fanconi anemia, and graft versus host disease. Splenic hypofunction is characterized by RBC inclusions in peripheral blood smears, “pits” on interference microscopy, and poor uptake of technetium on spleen scan. Patients with functional hyposplenism or asplenia are at increased risk of sepsis from encapsulated organisms.

Trauma.

Injury to the spleen may occur with left flank or abdominal trauma. Small splenic capsular tears may cause abdominal or referred left shoulder pain as a result of peritoneal irritation by blood. Larger tears result in more severe blood loss with similar pain and signs of hypovolemia. Previously enlarged spleens (as in infectious mononucleosis) are more likely to rupture with minor trauma.

Treatment of a small capsular injury should include careful observation with attention to changes in vital signs or abdominal findings, serial hemoglobin determinations, and the availability of prompt surgical intervention should a patient's condition deteriorate. RBC transfusion requirements should be minimal (<25?mL/kg/48?hr). These patients are usually hospitalized 10–14 days and have their activities restricted for months. A laparotomy with or without splenectomy is indicated for more marked abdominal bleeding, for clinical instability or deterioration, or when other organ damage is suspected. Partial splenectomy and splenic repairs should be substituted for total splenectomy when feasible.

Splenectomy.

Because of the risk of postoperative sepsis, splenectomy should be limited to specific indications. These include splenic rupture, anatomic defects, severe hemolytic anemias, immune cytopenias, metabolic storage diseases, secondary hypersplenism, and (rarely) surgical indications, including exposure of the left upper quadrant. The major long-term risk of splenectomy is sudden overwhelming infection (sepsis or meningitis). This risk is especially high in children younger than 5 yr at the time of surgery. The risk of sepsis is less after splenectomies performed for trauma, RBC membrane defects, and immune thrombocytopenia (2–4%) than when there is pre-existing immune deficiency (Wiskott-Aldrich syndrome, Hodgkin disease) or reticuloendothelial blockade (storage diseases, severe hemolytic anemias) (8–30%). Laparoscopic splenectomy has decreased morbidity and hospitalization time after splenectomy.

Encapsulated bacteria such as *Streptococcus pneumoniae* (>60% of cases), *Haemophilus influenzae*, and *Neisseria meningitides* account for more than 80% of post-splenectomy sepsis. Because the spleen is responsible for filtering the blood and early antibody responses, sepsis (with or without meningitis) can progress rapidly, leading to death within 12–24?hr of onset. Febrile splenectomized patients should be treated promptly with antibiotics. This should be initiated at home if access to definitive medical care will be delayed. A broad-spectrum cephalosporin (cefotaxime: 50?mg/kg q 8?hr) or vancomycin (10?mg/kg q 6?hr) to cover penicillin-resistant pneumococci is recommended until specific antibiotic susceptibility is known. Splenectomized patients are also at increased risk for contracting protozoal infections such as malaria and babesiosis.

Preoperative, intraoperative, and postoperative management may decrease the risk of post-splenectomy infection. It is important to be certain of the need for splenectomy and, if possible, to postpone the operation until the patient is 5 yr of age or older. Vaccination with pneumococcal, *H. influenzae*, and meningococcal vaccines before splenectomy may be helpful to reduce post-splenectomy sepsis. However, vaccine efficacy is lower in children younger than 2 yr and in immune-suppressed patients. In trauma cases, splenic repair or partial splenectomy should be considered in an attempt to preserve splenic function. Partial splenectomy or partial splenic embolization may be sufficient to ameliorate some forms of hemolytic anemia. Up to 50% of children whose spleen is removed for trauma have spontaneous splenosis; surgical splenosis (distributing small pieces of spleen throughout the abdomen) has been suggested as a way to decrease the risk of sepsis in patients whose splenectomy is necessitated by trauma. However, in both of these settings, the splenic tissue that regrows frequently has inadequate function. Prophylaxis with oral penicillin V (125?mg twice daily for children younger than 5 yr; 250?mg twice daily for children 5 yr or

older) should be given for at least 2 yr after splenectomy (to at least 6 yr of age). Prophylaxis may be continued into adulthood for higher-risk patients. Penicillin reduces the risk of pneumococcal sepsis in patients with hemoglobin SS, but other populations have not been well studied. Although the greatest risk is in the immediate postoperative period, reports of deaths occurring many years after

splenectomy suggest that the risk (and need for prophylaxis) may be lifelong. Other postoperative measures include patient and family education, wearing a medical information bracelet, and prompt evaluation and treatment of fevers. **REFERENCES**

Section 9 - *The Lymphatic System*

Bruce M. Camitta

Chapter 480 - Anatomy and Function of the Lymphatic System

The lymphatic system includes circulating lymphocytes, lymphatic vessels, lymph nodes, spleen, tonsils, adenoids, Peyer patches, and thymus. Lymph, an ultrafiltrate of blood, is collected by lymphatic capillaries that are present in all organs except the brain and the heart. These join to form progressively larger vessels that drain regions of the body. During their course, the lymphatic vessels carry lymph to the lymph nodes. In the nodes, lymph is filtered through sinuses where particulate matter and infectious organisms are phagocytosed, processed, and presented as antigens to surrounding lymphocytes. This results in stimulation of antibody production, T-cell responses, and cytokine secretion (see Chapter 113).

Lymph composition can vary with the site of lymph drainage. It is usually clear, but drainage of lymph from the intestinal tract may be milky (chylous) because of the presence of fats. The protein content is intermediate between an exudate and a transudate. The protein level may be increased with inflammation or in lymph from the liver or intestines. Lymph also contains variable numbers of lymphocytes.

Chapter 481 - Abnormalities of Lymphatic Vessels

Abnormalities of the lymph vessels may be congenital or acquired. Signs and symptoms may result from increased lymphatic tissue mass or from leakage of lymph. *Lymphangiectasia* is a dilation of the lymphatics. Pulmonary lymphangiectasia causes respiratory distress (see Chapter 383). Involvement of the intestinal lymphatics causes hypoproteinemia and lymphocytopenia secondary to loss of lymph into the intestines (see Chapter 320.10). *Lymphangioma* (cystic hygroma) is a mass of dilated lymphatics. Some of these lesions also have a hemangiomatous component (see Chapter 497). Because surgical treatment is complicated by a high incidence of recurrence, intralesional sclerosing with OK-432, a streptococcal derivative, has been used in selected patients. *Lymphatic dysplasia* may cause multisystem problems. These include lymphedema, chylous ascites, chylothorax, and lymphangiomas of bone, lung, or other locations.

Lymphedema is caused by obstruction of lymph flow. Congenital lymphedema may be found in Turner syndrome, Noonan syndrome, and the autosomal dominantly inherited Milroy disease. *Lymphedema praecox* causes progressive lower extremity edema, usually in females (10–25 yr old). Lymphedema has also been found in association with intestinal lymphangiectasia, cerebrovascular malformation, ptosis, yellow dystrophic nails, distichiasis, and cholestasis. Acquired obstruction of the lymphatics can result from tumor, postirradiation fibrosis, filariasis, and postinflammatory scarring. Injury to the major lymphatic vessel can cause collection of lymph fluid in the abdomen (chylous ascites) and chest (chylothorax).

Lymphangitis is an inflammation of the lymphatics draining an area of infection. On examination, tender red streaks extend proximally from the infected site. Regional nodes may also be enlarged and tender. *Staphylococcus aureus* and group A streptococci are the most frequent pathogens.

Chapter 482 - Lymphadenopathy

Most lymph nodes are not palpable in the newborn infant. With antigenic exposure, lymphoid tissue increases in volume so that cervical, axillary, and inguinal nodes are often palpable during childhood. They are not considered enlarged until their diameter exceeds 1?cm for cervical or axillary nodes and 1.5?cm for inguinal nodes. Other lymph nodes usually are not palpable or visualized with plain radiographs.

Lymph node enlargement is caused by proliferation of normal lymphoid elements or to infiltration by malignant or phagocytic cells. In most patients, a careful history and a complete physical examination suggest the proper diagnosis (Box 482–1). Nonlymphoid masses (cervical rib, thyroglossal cyst, branchial sinus or cystic hygroma, goiter, sternomastoid muscle tumor, neurofibroma) occur frequently in the neck and less often in other areas. Acutely infected nodes are usually tender. There may also be erythema and warmth of the overlying skin. Fluctuance suggests abscess formation. Tuberculous nodes may be matted. With chronic infection, most of the just described signs are not

Box 482-1. Evaluation of Possible Adenopathy

1. Is the swelling a lymph node?
2. Is the node enlarged?
3. What are the characteristics of the node?
4. Is the adenopathy local or generalized?

present. Tumor-bearing nodes are usually firm and nontender and may be matted or fixed to the skin or underlying structures.

Generalized adenopathy (enlargement of more than two noncontiguous node regions) is caused by systemic disease (Box 482–2) and is often accompanied by abnormal physical findings in other systems. In contrast, localized adenopathy is most frequently the result of infection in the involved node and/or its drainage area (Boxes 482–3 and 482–4).

Regional lymphadenitis, as a result of infectious agents other than bacteria, may be characterized by atypical anatomic areas, a prolonged course, a draining sinus, lack of prior pyogenic infection, and unusual clues in the history (cat scratches, tuberculosis exposure, venereal disease).

A firm fixed node should always raise the question of malignancy, regardless of the presence or absence of systemic symptoms or other abnormal physical findings.

Evaluation and treatment of lymphadenopathy is guided by the probable etiologic factor, as determined from the history and physical examination. For example, many patients with cervical adenopathy have a history of viral infection and need no intervention. If a bacterial infection is suspected, antibiotic treatment covering at least streptococci and staphylococci is indicated. Surgical drainage is required if an abscess forms. The size of involved nodes should be documented before treatment. Failure to decrease in size within 10–14 days suggests the need for further evaluation. This may include complete blood cell count with differential; Epstein-Barr virus, cytomegalovirus, *Toxoplasma*, and cat-scratch disease titers; antistreptolysin O or anti-DNAase serologic tests; tuberculin skin test; and chest radiograph. If these are not diagnostic, consultation with infectious disease or oncology specialists may be helpful. Biopsy should be considered if there is persistent or unexplained fever, weight loss, night sweats, hard nodes, or fixation of the nodes to surrounding tissues. Biopsy may also be indicated if there is an increase in size over baseline in 2 wk, no decrease in size in 4–6 wk, no regression to "normal" in 8–12 wk, or the development of new signs and symptoms.

Box 482-2. Common Causes of Generalized Lymphadenopathy

AUTOIMMUNE DISEASES

Dermatomyositis, lupus erythematosus, rheumatoid arthritis

DRUG REACTIONS

INFECTIONS

Cytomegalovirus, histoplasmosis, HIV, HTLV, mononucleosis, rubella, rubeola, toxoplasmosis, varicella, tuberculosis

LIPID STORAGE DISEASES

Gaucher disease, Niemann-Pick disease

MALIGNANCIES

Primary: histiocytic disorders, Hodgkin disease, lymphoproliferative disease (PTLPD), non-Hodgkin lymphoma, post transplant lymphoproliferation

Metastatic: leukemia, neuroblastoma, rhabdomyosarcoma

OTHER

Castleman disease, sarcoidosis, serum sickness

Box 482-3. Drainage Areas of Regional Nodes

ABDOMINAL AND PELVIC

Abdomen, lower extremity, pelvic organs

AXILLARY

Arm, breast, chest wall, hand, upper and lateral abdominal wall

CERVICAL

External ear, larynx, parotid, superficial tissues of the head and thyroid, tongue, trachea

EPITROCHLEAR

Forearm, hand

ILIAC

Bladder, lower abdomen, part of the genitalia, urethra

INGUINAL

Gluteal region, lower anal canal, lower extremity, perineum, scrotum and penis in males, skin of the lower abdomen, vulva and vagina in females

lower extremity, perineum, scrotum and penis in males, skin of the lower abdomen, vulva and vagina in females

MEDIASTINAL

Thoracic viscera

OCCIPITAL

Part 21 - Cancer and Benign Tumors

Chapter 483 - Epidemiology of Childhood and Adolescent Cancer

1679

James G. Gurney
Melissa L. Bondy

Only about 1% of new cancer cases in the United States occur in children age 19 yr or younger (~12,400 cases/yr), yet children dying of cancer lose an average of 69.5 yr of life, a span far exceeding the average loss from any adult cancer. Despite impressively improved 5-yr survival probabilities for children diagnosed with cancer, from 56% in 1974 to over 75% in 2000, malignant neoplasms remain the second leading death cause (10.6% of all deaths) among 1–14 yr olds in the United States. Although most pediatric cancer patients survive their disease and the associated treatment, the long-term consequences of cure, the **late adverse effects**, are only now becoming a focus of clinical research. The number of children alive today who either have or had a malignancy is difficult to determine. Prevalence estimates from the National Cancer Institute for U.S. children age 19 yr or younger range from 90,000–174,000.

Pediatric cancers differ markedly from adult malignancies in their prognosis and their distribution by histology and tumor site. Acute lymphoblastic leukemia, brain cancers, lymphomas, and sarcomas of soft tissue and bone predominate in children and adolescents (Table 483–1). In adults, in contrast, epithelial tumors of organs such as lung, colon, breast, and prostate are most common. Unlike incidence patterns in adults where cancer rates tend to rapidly increase with increasing age, relatively wide age variability exists during development, with two peaks, in early childhood and in adolescence (Fig. 483–1). During the 1st yr of life, **embryonal tumors** such as neuroblastoma, Wilms' tumor (nephroblastoma), retinoblastoma,

rhabdomyosarcoma, and medulloblastoma are most common (Fig. 483–2). These tumors, which are likely congenital, occur far less often among older children, whose developmental processes and cell differentiation have slowed considerably, and are extremely unusual in adults. Embryonal tumors combine with acute leukemias, non-Hodgkin lymphomas, and gliomas, which together peak in incidence from 2–5 yr of age, for the highest cancer incidence during childhood and adolescence other than in infancy. As children age, especially after they pass puberty, bone malignancies, Hodgkin disease, **gonadal germ cell malignancies** (testicular and ovarian carcinomas), and various carcinomas such as thyroid cancer and malignant melanoma increase in incidence. It appears that adolescence is a transitional period between the common early childhood malignancies and characteristic carcinomas of adulthood.

Pediatric oncologists face unique challenges because treatment with radiation, surgery, and chemotherapy may adversely affect growth and development and may cause serious long-term medical and psychosocial effects. Given the relative rarity of specific types of childhood cancer and the sophisticated technology and expertise required for diagnosis, treatment, and monitoring of late effects, all children with cancer should be treated on standardized clinical protocols in clinical research settings whenever possible.

PNET = primitive neuroectodermal tumor. From Ries LAG, Eisner MP, Kosary CI, et al (editors): *SEER Cancer Statistics Review, 1973–1998*. Bethesda MD, National Cancer Institute, 2001; http://seer.cancer.gov/childhood/

Promoting such treatment, the Children's Oncology Group facilitates clinical, biologic, and epidemiologic research in 238 affiliated institutions in North America. These centers have the required facilities and expertise and are committed to learning more about and defining the optimal treatment of pediatric malignancy through participation in national clinical trials. Such coordinated treatment efforts have substantially increased survival for many children with cancer. The continuing poor prognosis, however, for specific malignancies such as acute myeloid leukemia, high-risk neuroblastoma, and many brain cancers demands continuing concerted and coordinated clinical research efforts. So, too, does the need for clinical and epidemiologic research on the late effects of therapy.

RISK FACTORS

Childhood neoplasms comprise a diverse array of malignant (cancers) and nonmalignant tumors arising from disorders of genetic processes involved in control of cellular growth and development. Although a number of genetic conditions are associated with elevated risks for childhood cancer, such conditions are believed to account for less than 5% of all occurrences. The most notable genetic conditions that impart childhood cancer susceptibility are neurofibromatosis types 1 and 2, Down syndrome, Beckwith-Wiedemann syndrome, tuberous sclerosis, von Hippel-Lindau disease, xeroderma pigmentosum, ataxia-telangiectasia, nevus basal cell carcinoma syndrome, and Li-Fraumeni (*P53*) syndrome.

Figure 483-2 Incidence of the most common types of cancer in children by age. The cumulative incidence is shown as a dashed line. (Courtesy of Archie Bleyer, MD.)

TABLE 483-2 -- Known Risk Factors for Selected Pediatric Cancers

(Not Available)
From Gurney JG, Bondy ML: Epidemiologic research methods and childhood cancer. In Pizzo PA, Poplack DG (editors): Principles and Practice of Pediatric Oncology, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2001, pp 13–20.

Because of the relatively minor role of directly heritable conditions, research efforts in cancer epidemiology are moving to the exploration of potential interactions between genetic susceptibility traits and environmental exposures, but very few established environmental causes of childhood cancer are known (Table 483–2 (Table Not Available)). Risk factors for the major pediatric cancers such as ionizing radiation exposure and several chemotherapeutic agents explain very few cases overall. Among environmental exposures studied, but currently without convincing evidence for a causal role, are non-ionizing power frequency electromagnetic fields, pesticides, parental occupational chemical exposures, dietary factors, and environmental cigarette smoke. Pediatric cancers have been associated with some viruses whose etiologic importance remains unclear, such as the polyomaviruses (BK, JC, and SV 40) that have been associated with brain cancer, and Epstein-Barr virus with non-Hodgkin lymphoma. The connection, also, of transplacental fetal exposures to pediatric cancer is largely unestablished in humans, with the exception of maternal diethylstilbestrol intake during pregnancy and subsequent vaginal cancer in adolescent female offspring. In notable contrast to adult epithelial tumors, a very low fraction of pediatric cancers, at least based on current evidence, appears to be explainable from known environmental exposures.

Chapter 484 - Molecular and Cellular Biology of Cancer

Laura L. Worth

Cancer is a complex of diseases arising from alterations that can occur in a wide variety of genes. Alterations in normal cellular processes such as signal transduction, cell cycle control, DNA repair, cellular growth and differentiation, translational regulation, senescence, and apoptosis (programmed cell death) can result in a malignant phenotype.

GENES INVOLVED IN ONCOGENESIS

Two major classes of genes have been implicated in the development of cancer: oncogenes and tumor suppressor genes. **Proto-oncogenes** are cellular genes that are important for normal cellular function and code for various proteins, including transcriptional factors, growth factors, and growth factor receptors.

These proteins are vital components in the network of signal transduction that regulate cell growth, division, and differentiation. Proto-oncogenes can be altered to form **oncogenes**, genes that when translated can result in the malignant transformation of a cell.

The three main mechanisms by which proto-oncogenes can be activated include amplification, point mutations, and translocation (Table 484–1). *MYC*, which codes for a protein that regulates transcription, is an example of a proto-oncogene that is activated by amplification. Patients with neuroblastoma in which the *MYC* gene is amplified 10–300 fold have a poorer outcome. Point mutations can also activate proto-oncogenes. The *NRAS* proto-oncogene codes for a guanine nucleotide-binding protein with guanosine triphosphatase activity that is important in signal transduction and is mutated in 25–30% of acute nonmyelogenous leukemias, resulting in a constitutively active protein. The RET protein is a transmembrane tyrosine kinase receptor that is important in signal transduction. A point mutation in the *RET* gene results in the constitutive activation of a tyrosine kinase, as found in multiple neoplasia syndromes and familial thyroid carcinoma. The third mechanism by which proto-oncogenes become activated is chromosomal translocation. In some leukemias and lymphomas, transcription factor controlling sequences are relocated in front of T-cell receptors or immunoglobulin genes, resulting in unregulated transcription of the genes and leukemogenesis. Chromosomal translocations can also result in **fusion genes;** transcription of the fusion gene can result in the production of a chimeric protein with new and potentially oncogenic activity. Examples of cancers associated with fusion genes include the childhood solid tumors such as Ewing sarcoma [t(11;22)] and alveolar rhabdomyosarcoma [t(2;13) or t(1;13)]. The translocations result in novel proteins that are useful as diagnostic markers. The best described translocation in leukemia is the **Philadelphia chromosome t(9;22)**, which results in the BCR/ABL protein found in chronic myelogenous leukemia. This translocation results in a tyrosine kinase protein that is constitutively activated. In addition, the protein is localized to the cytoplasm instead of the nucleus, exposing the kinase to a new spectrum of substrates.

Alteration in the regulation of tumor suppressor genes is another mechanism involved in oncogenesis. Tumor suppressor genes are important regulators of cellular growth and programmed cell death or apoptosis. They have been called recessive oncogenes because the inactivation of both alleles of a tumor suppressor gene is required for expression of a malignant phenotype.

Knudson's **"two-hit" model of cancer development** was based on the observation of the behavior of the tumor suppressor gene *RB*. In sporadic cases of retinoblastoma, both alleles of the *RB* gene must be inactivated. However, in familial cases, children inherit an inactivated allele from one parent and consequently require the inactivation of the only remaining normal allele. This helps explain why familial cases of retinoblastoma

TABLE 484-1 -- **Oncogene Activation in Pediatric Tumors**

Mechanism	Chromosome	Genes	Protein Function	Tumor
Chromosomal translocation	t(9;22)	*BCR-ABL*	Chimeric tyrosine kinase	CML, ALL
	t(1;19)	*E2A-PBX1*	Chimeric transcription factor	Pre-B ALL
	t(14;18)	*CMYC*	Transcription factor	Burkitt lymphoma
	t(15;17)	*APL-RARa*	Chimeric transcription factor	APL
Gene amplification	Amplicon	*NMYC*	Transcription factor	Neuroblastoma
	Amplicon	*EGFR*	Growth factor receptor, tyrosine kinase	Glioblastoma
Point mutation	1p	*NRAS*	GTPase	AML
	10q	*RET*	Tyrosine kinase	MEN2

ALL = acute lymphocytic anemia; AML = acute myelocytic leukemia; APL = acute promyelocytic leukemia; CML = chronic myelocytic leukemia; MEN2 = multiple endocrine neoplasia type 2.

present earlier in childhood than do sporadic cases, because only one “hit” is required.

Another major tumor suppressor protein is p53, which is known as the “guardian of the genome” because it detects the presence of chromosomal damage and prevents the cell from dividing until repairs have been made. In the presence of damage beyond repair, p53 initiates apoptosis and the cell dies. More than 50% of all tumors have abnormal p53 proteins. Mutations in the *P53* gene are important in many cancers, including breast, colorectal, lung, esophageal, stomach, ovarian, and prostatic carcinomas as well as gliomas, sarcomas, and some leukemias.

SYNDROMES PREDISPOSING TO CANCER

Several syndromes are associated with an increased risk of developing malignancies, which can be characterized by different mechanisms (Table 484–2). One mechanism involves the inactivation of tumor suppressor genes, such as *RB* in familial retinoblastoma. Interestingly, patients with retinoblastoma in which one of the alleles is inactivated throughout all of the patient's cells are at very high risk for developing osteosarcoma. A familial syndrome, Li-Fraumeni syndrome, in which one mutant *P53* allele is inherited, has also been described in which patients can develop sarcomas, leukemias, and cancers of the breast, bone, lung, and brain. Neurofibromatosis is a condition characterized by the proliferation of cells of neural crest origin, leading to neurofibromas. These patients are at a higher risk of developing malignant schwannomas and pheochromocytomas. Neurofibromatosis is often inherited in an autosomal dominant fashion, although 50% of the cases present without a family history and occur secondary to the high rate of spontaneous mutations of the *NF1* gene.

A second mechanism responsible for inherited predisposition to develop cancer involves defects in DNA repair. Syndromes associated with an excessive number of broken chromosomes due to repair defects include Bloom syndrome (short stature, photosensitive telangiectatic erythema), ataxia-telangiectasia (childhood ataxia with progressive neuromotor degeneration), and Fanconi anemia (short stature, skeletal and renal anomalies, pancytopenia). Because of the decreased ability to repair chromosomal defects, cells accumulate abnormal DNA that results in significantly increased rates of cancer, especially leukemia. Xeroderma pigmentosum likewise increases the risk of skin cancer, owing to defects in repair of DNA damaged by ultraviolet light. These disorders display an autosomal recessive pattern.

A third category of inherited cancer predisposition is characterized by defects in immune surveillance. This group includes patients with Wiskott-Aldrich syndrome, severe combined immunodeficiency, common variable immunodeficiency, and the X-linked lymphoproliferative syndrome. The most common types of malignancy in these patients are lymphoma and leukemia. Cure rates for immunodeficient children with cancer are much poorer than for immunocompetent children with similar

TABLE 484-2 -- **Familial or Genetic Susceptibility to Malignancy**

Disorder	Tumor/ Cancer	Comment
Chromosomal Syndromes		
Chromosome 11p —(deletion) with sporadic aniridia	Wilms tumor	Associated with genitourinary anomalies, mental retardation, *WT1* gene
Chromosome 13q —(deletion)	Retinoblastoma, sarcoma	Associated with mental retardation, skeletal malformations: autosomal dominant (bilateral) or sporadic new mutation, *RB1*gene
Trisomy 21	Lymphocytic or nonlymphocytic leukemia	Risk is 15 times normal
Klinefelter syndrome (47, XXY)	Breast cancer, extragonadal germ cell tumors	
Gonadal dysgenesis XO/ XY	Gonadoblastoma	Gonads must be removed; 25% chance of gonadal malignancy
Trisomy 8	Preleukemia	
Noonan syndrome	Schwannoma, myelodysplasia	
Monosomy 5 or 7	Myelodysplastic syndromes	Recurrent infections may precede neoplasia
DNA Fragility		
Xeroderma pigmentosum	Basal, squamous cell skin cancers	Autosomal recessive; failure to repair solar-damaged DNA
Fanconi anemia	Leukemia	Autosomal recessive; 10% risk for acute myelogenous leukemia; chromosome fragility, positive diepoxybutane test result
Bloom syndrome	Leukemia, lymphoma	Autosomal recessive; chromosome fragility; high risk for malignancy

Ataxia-telangiectasia	Lymphoma, leukemia	Autosomal recessive; sensitive to x-radiation, radiomimetic drugs; chromosome fragility
Dysplastic nevus syndrome	Melanoma	Autosomal dominant
Immunodeficiency Syndromes		
Wiskott-Aldrich syndrome	Lymphoma, leukemia	Immunodeficiency; X-linked recessive
X-linked immunodeficiency (Duncan syndrome)	Lymphoma	Epstein-Barr virus is inciting agent
X-linked agammaglobulinemia	Lymphoma, leukemia	Immunodeficiency
Severe combined immunodeficiency	Leukemia, lymphoma	Immunodeficiency; X-linked recessive
Others		
Neurofibromatosis 1	Neurofibroma, optic glioma, acoustic neuroma, astrocytoma, meningioma, pheochromocytoma, sarcoma	Autosomal dominant; *NF1* gene
Neurofibromatosis 2	Bilateral acoustic neuromas, meningioma	Autosomal dominant; *NF2*gene
Tuberous sclerosis	Fibroangiomatous nevi, myocardial rhabdomyoma	Autosomal dominant
Hemochromatosis	Hepatoma	Cirrhosis; autosomal dominant/ recessive
Retinoblastoma	Sarcoma	Increased risk of secondary malignancy 10 – 20 yr later, *RB1* gene
Glycogen storage disease I	Hepatic adenoma	Usually with cirrhosis, autosomal recessive
Familial adenomatous polyposis coli	Adenocarcinoma of colon	Autosomal dominant, *APC* gene
Gardner syndrome	Adenocarcinoma of colon; skull and soft tissue tumors	Autosomal dominant, *APC* gene
Peutz-Jeghers syndrome	Gastrointestinal carcinoma, ovarian neoplasia	Autosomal dominant
Hemihypertrophy ± Beckwith's syndrome	Wilms tumor, hepatoblastoma, adrenal carcinoma	25% develop tumor, most in first 5 yr of life
Tyrosinemia, galactosemia	Hepatic carcinoma	Nodular cirrhosis; autosomal recessive
Multiple endocrine neoplasia syndrome, type I (Wermer syndrome)	Parathyroid adenoma, pancreatic islet tumor, pituitary adenoma carcinoid	Autosomal dominant; Zollinger-Ellison syndrome
Multiple endocrine neoplasia syndrome, type II (Sipple syndrome)	Medullary carcinoma of the thyroid, hyperparathyroidism, pheochromocytoma	Autosomal dominant; monitor calcitonin and calcium levels
Multiple endocrine neoplasia, type III (multiple mucosal neuroma syndrome)	Mucosal neuroma, pheochromocytoma, medullary thyroid carcinoma; Marfan habitus; neuropathy	Autosomal dominant
Rendu-Osler-Weber syndrome	Angioma	Autosomal dominant
von Hippel-Lindau disease	Hemangioblastoma of the cerebellum and retina, pheochromocytoma, renal cancer	Autosomal dominant, mutation of tumor-suppressor gene, *VHL* gene
Cancer family syndrome	Colonic, uterine carcinoma	Autosomal dominant
Li-Fraumeni syndrome	Bone, soft tissue sarcoma, breast	Mutation of *P53* tumor-suppressor gene, autosomal dominant
BRCA1 and 2	Breast, ovarian	DNA repair defect

malignancies, suggesting a role for the immune system in cancer treatment as well as in cancer prevention.

OTHER FACTORS ASSOCIATED WITH ONCOGENESIS

Viruses.

Several viruses have been implicated in the pathogenesis of malignancy. The association of the Epstein-Barr virus (EBV) with Burkitt lymphoma and nasopharyngeal carcinoma was identified more than 30 yr ago, but EBV infection alone is not sufficient for malignant transformation. EBV is also associated with mixed cellularity and lymphocyte-depleted Hodgkin disease as well as some T-cell lymphomas, which is particularly intriguing because EBV normally does not infect T lymphocytes. The most conclusive evidence for a role of EBV in lymphogenesis is the direct causal role of EBV for B-cell lymphoproliferative disease in

immunocompromised persons, especially those with AIDS.

As is the case with adults, children who are chronically infected with hepatitis B (HBsAg-positive) have a greater than 200-fold risk of developing hepatocellular carcinoma. In adults, the latency period between viral infection and the development of hepatocellular carcinoma approaches 20 yr. However, in children who acquire the viral infection through perinatal transmission, the latency period can be as short as 6–7 yr. The additional factors that are required for malignant transformation of the virally infected hepatocytes are not clear. Hepatitis C virus infection is also a risk factor for hepatocellular carcinoma and is also associated with splenic lymphoma.

Nearly all cervical carcinomas contain human papillomaviruses (HPV). High-risk papillomaviruses include types 16 and 18 but also 31, 33, 35, 45, and 56, which are also most commonly found in women without lesions. The low-risk papillomaviruses, including types 6 and 11 that are most commonly found in genital warts, are almost never associated with malignancies. Like other virus-associated cancers, the presence of HPV alone is not sufficient to cause malignant transformation. The mechanism by which HPV 19 induces malignant transformation is thought to involve *P53* and *RB* tumor suppressor genes, which regulate the cell cycle by acting as gatekeepers of the G1/S and G2/M checkpoints. By interfering with these proteins, HPV alters the regulation of cell growth.

Human herpesvirus 8 (HHV8) is associated with Kaposi sarcoma, primary effusion B-cell lymphoma, and the plasma cell variant of Castleman disease, all of which occur primarily in persons with AIDS. Human T-cell leukemia virus type 1 (HTLV-1) is associated with adult T-cell leukemia and lymphoma.

Genomic Imprinting.

The development of cancer has also been linked to genomic imprinting, which is the selective inactivation of one of two alleles of a certain gene. The inactivated gene is determined by whether the gene is inherited from the mother or father. For example, normally the maternal *IGF2* (insulin-like growth factor receptor 2) gene is inactivated. The inactivation is thought to be secondary to methylation of specific CpG sequences upstream of the IGF2 promoter, which interferes with the transcription of the *IGF2* gene. In some Wilms tumors, there is loss of methylation in the upstream area of the maternal gene, which, in turn, allows transcript expression of the maternal *IGF2* gene. At the same time the *H19* gene (whose function is not yet clear), a previously actively transcribed maternal gene, is silenced by methylation. Beckwith-Weidemann syndrome, an overgrowth syndrome characterized by macrosomia, macroglossia, hemihypertrophy, omphalocele, and renal anomalies, is associated with an increased risk of Wilms tumor, hepatoblastoma, rhabdomyosarcoma, neuroblastoma, and adrenal cortical carcinoma. The increased risk in developing cancer is associated with changes in the methylation pattern of genes on the 11p15 chromosome.

Telomerase.

Telomeres are a series of tens to thousands of TTAGGG repeats at the ends of chromosomes that are important for stabilizing the chromosomal ends and limiting breakage, translocation, and loss of DNA maternal. With DNA replication there is a progressive shortening of telomere length, which is a hallmark of cellular aging and may be a senescence signal. In some instances, telomerase, which is an enzyme that adds telomeres to the ends of chromosomes, becomes active. The addition of telomeres occurs in immortalized cell lines and most tumor types and, as a consequence, these cells may have a survival advantage allowing them to undergo additional cell divisions. Therapy aimed at inhibition of telomerase activity may result in cell death.

Chapter 485 - Principles of Diagnosis

Archie Bleyer

Symptoms and physical findings are important in the recognition of malignant diseases and life-threatening benign tumors in children and adolescents. In addition to the classic manifestations, any persistent, unexplained symptom or sign should be evaluated as potentially emanating from a cancerous or precancerous condition. As part of the diagnostic evaluation, the pediatrician and pediatric oncologist must convey the diagnosis to the patient and family in a sensitive and informative manner.

SIGNS AND SYMPTOMS

In contrast to the classic warning signs of cancer in adults, there is no established set of similar symptoms and signs of cancer in children, although the most frequent cancers in children suggest 10 signs and symptoms that are helpful for early recognition (Box 485–1). This lack of explicit criteria is caused by multiple factors. The symptoms and signs of cancer are more variable and nonspecific in children. Most childhood cancers originate from deeper structures in the body, from the parenchyma or organs rather than from epithelial layers that compose the skin and that line the ducts and glands of organs. In children, metastases are present at diagnosis in approximately 80% of cases, whereas only about 20% of adults have evidence of metastases at diagnosis. In children, therefore, the presenting symptoms or signs are more likely to be caused by metastases than by the primary tumor. Thus, the signs of cancer in children are frequently attributed to other causes before the malignancy is recognized. There are several additional but less common signs and symptoms of cancer in children (Box 485–2).

Diffuse enlargement of the pons is a radiographic finding, usually on MRI, which is nearly always indicative of malignant disease and may be considered pathognomonic (Fig. 485–1). Diffuse, not local, enlargement of the pons is regarded as astrocytoma and treated accordingly without tissue biopsy, in part because or the risk and difficulty of procedure on this part of the brain. The hematopoietic sign of more than one abnormal hematopoietic lineage is primarily a laboratory observation in which more than one of the three blood cell lineages (leukocytes, erythrocytes, and platelets) are affected. Related signs may also be apparent on physical examination. A white pupillary reflex (Fig. 485–2), instead of the usual red reflection from incident light, is almost pathognomonic for retinoblastoma, although astrocytic hamartoma, Coats disease, and posterior persistent hyperplastic vitreous (PPHV) may mimic this finding.

Box 485-1. The Most Frequent Signs and Symptoms of Cancer in Children and Adults

ADULTS	CHILDREN
(American Cancer Society, 1950s)	(University of Texas M.D. Anderson Cancer Center)
Change in bowel or bladder habits	Abdominal mass
Blood in stool	Persistent lymphadenopathy
Lump in breast or elsewhere	More than one abnormal hematopoietic lineage
Hoarseness or nagging cough	Specific neurologic deficit
Difficulty in swallowing	Increased intracranial pressure
Sore that will not heal	Diffuse enlargement of pons
Change in wart or mole	Proptosis
	White pupillary reflex
	Unilateral knee or shoulder pain or swelling
	Vaginal bleeding or mass

Physical Examination.

The physical examination should focus on the tissues and organ systems that are most likely to be affected by cancer in children (Table 485–1). Accordingly, paying

particular attention to blood, brain, belly, and bone—the

Modified from Vietti TJ, Steuber CP: Clinical assessment and differential diagnosis of the child with suspected cancer. In Pizzo PA, Poplack DG (editors): Principles and Practice of Pediatric Oncology, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2002, pp 149–59.

4 Bs—is helpful in eliciting evidence of malignancy by physical examination.

Abnormalities of the hematopoietic system are manifested as (1) pallor, which indicates anemia; (2) bleeding from orifices, petechiae, purpura, and ecchymosis, which indicate thrombocytopenia and disseminated intravascular coagulation; (3) cellulitis and other infection, which indicate leukopenia; (4) skin nodules, which indicate leukocytosis; and (5) other abnormalities of the formed elements of the blood. Abnormalities of the lymphatic system include lymphadenopathy (Fig. 485–3), superior vena cava syndrome, or respiratory distress when the patient is in a supine position resulting from upper anterior mediastinal mass or thymic enlargement (Fig. 485–4). Enlargement of the cervical lymph nodes is common in children with infection and in patients with lymphoma. Persistent or progressive enlargement of lymph nodes, often painless, is suggestive of lymphoma and indicates the need for biopsy.

Abnormalities of the central nervous system that indicate cancer include decreased level of consciousness, paresis of the sixth nerve, and increased intracranial pressure, which may be diagnosed by the presence of papilledema (Fig. 485–5). Any focal neurologic deficit in the motor or sensory system, especially a decrease in cranial nerve function, should prompt further investigation for malignancy.

Abnormalities of the embryonal system are usually apparent on physical examination as organomegaly or an abdominal mass. However, an unexplained mass in any area of the body should be considered malignant until proven otherwise. Retinoblastoma is, of course, usually manifest as a white pupillary reflex (see Fig. 485–2). In neonates, “blueberry muffin” spots on the skin may be neuroblastoma. A sacrococcygeal mass is usually a teratoma that may undergo malignant transformation if it is not removed.

Figure 485-1 Brain stem tumor apparent on MRI. (From Sinniah D, D'Angio GJ, Chatten J, et al: *Atlas of Pediatric Oncology*. London, Arnold, 1996.)

Figure 485-2 White pupillary reflex. (From Sinniah D, D'Angio GJ, Chatten J, et al: *Atlas of Pediatric Oncology*. London, Arnold, 1996.)

Age-Related Manifestations.

Because the types of cancer in children occur at specific ages, the physician should tailor the history and physical examination based on the age of the child. The embryonal tumors, including neuroblastoma, usually occur during the first 2 yr of life (see Fig. 483–2). From 2–5 yr of age, acute lymphoblastic leukemias, non-Hodgkin's lymphoma, and gliomas peak in incidence. During adolescence, bone tumors, Hodgkin disease, and the gonadal and connective tissue tumors predominate. Hence, for infants and toddlers, special attention should be paid to the possibility of embryonal and intra-abdominal tumors (i.e., Wilms tumor, retinoblastoma, teratoma, neuroblastoma, and liver tumors). Preschool-aged and early school-aged children showing compatible signs and symptoms should be specifically evaluated for leukemia, lymphoma, and brain tumors. Adolescents require assessment for sarcomas and genital or gonadal malignancies, as well as for

Hodgkin disease.

IMPORTANCE OF EARLY DETECTION

Because most of childhood cancers are curable, early detection is paramount. In addition, there are several types of cancer for which less therapy is indicated for early-stage disease than for advanced disease. Indeed, early detection often minimizes the amount and duration of treatment required for cure and may therefore not only lead to a higher potential for cure but also spare the patient intensive or prolonged therapy.

The prognosis of malignancy in children depends primarily on tumor type, extent of disease at diagnosis, and rapidity of response to treatment. Early diagnosis helps to ensure that appropriate therapy is given in a timely fashion and, hence, optimizes the chances of cure. Because most physicians in general practice rarely encounter children with cancer, they should investigate the possibility of malignancy when they encounter an atypical course of a common childhood condition.

Delayed diagnosis is particularly likely in certain clinical situations. The cardinal symptom of both osteosarcoma and Ewing sarcoma is localized and usually persistent pain. Because these

TABLE 485-1 -- **Organ Systems and Tissues of the Most Common Cancers in Children**

Type of Cancer	Proportion of All Cancers (%)

tumors occur during the 2nd decade of life, a time of increased physical activity, patients often associate the pain with an episode of trauma. Prompt radiologic evaluation can help confirm the diagnosis. Tumors of the nasopharynx or middle ear may mimic infection. Prolonged unexplained ear pain, nasal discharge, retropharyngeal swelling, and trismus should be investigated as possible signs of malignancy.

Early symptoms of leukemia may be limited to low-grade fever or bone and joint pain. Blood counts, with particular attention to the presence of normocytic anemia or mild thrombocytopenia, may indicate the need for bone marrow examination, even when leukemic blast cells are not seen in the peripheral blood smear. Malignancy can also occur in neonates and should be considered in children with masses in any area or with “blueberry muffin” spots on their skin; the latter sign indicates neuroblastoma.

STAGING

When a patient is suspected to have a malignant neoplasm, the immediate goal is to determine its type and extent. A tentative diagnosis can often be established on the basis of the patient's age, presenting symptoms, and the location of a suspected mass. A thorough search for metastatic disease usually precedes biopsy of a suspicious lesion. The surgeon can make a more informed choice between an attempt at complete resection and a more limited procedure when the presence or likelihood of disseminated disease is known. The appropriate preoperative studies depend on the tentative diagnosis. Several noninvasive techniques (e.g., CT and MRI) are useful in evaluating patients

Figure 485-4 Anterior upper mediastinal mass due to non-Hodgkin lymphoma. (From Sinniah D, D'Angio GJ, Chatten J, et al: *Atlas of Pediatric Oncology*. London, Arnold, 1996.)

Figure 485-5 Papilledema. (From Sinniah D, D'Angio GJ, Chatten J, et al: *Atlas of Pediatric Oncology*. London, Arnold, 1996.)

for the presence of metastatic lesions; also, bone marrow aspiration, biopsy, or both may be needed. These studies are also used in assessing the disease stage, information that is critical in determining the prognosis and developing a treatment plan.

HISTOPATHOLOGY

Central to the diagnosis of any tumor is histologic examination of specimens. The initial specimen of tumor tissue should be obtained under conditions that allow for a full range of pathologic studies. In some cases, such as suspected lymphomas, fresh tissue may be required for special studies. Some of these studies are time consuming; thus, it is often impossible to discuss the specific diagnosis with the patient's family immediately after surgery.

In many cases, the diagnosis can be ascertained by means of a fine-needle biopsy, thus eliminating the need for an incision or major operation. However, a diagnosis based on the results of a fine-needle biopsy requires the availability of an experienced radiologist and an experienced cytologist and usually can be performed only at major medical centers. Similarly, minimally invasive surgery utilizing endoscopic techniques is commonly performed in patients with abdominal and thoracic masses. At the time of biopsy, excision, or exploration the surgeon must search carefully for evidence of regional dissemination to lymph node groups or to adjacent organs. If total resection is attempted, the pathologist must carefully examine the margins for microscopic residual tumor because this information is

needed for determining subsequent treatment.

Explaining the Diagnostic Evaluation to Pediatric Patients and Their Families.

The diagnostic and treatment plan must be carefully explained to parents and, if old enough to understand, to the patient. An honest discussion of the facts is the best policy. Children should be told all information that they can understand and would find useful or that they express a desire or wish to know. Effects of treatment, such as the possible need to amputate a limb, loss of hair during chemotherapy, and possible temporary or permanent functional impairment must be anticipated and fully discussed. The possibility and probability of death from cancer should be covered in an age-appropriate manner. It is usually necessary to repeat explanations several times before distraught family members fully and uniformly understand what is being communicated. Throughout treatment, parents, patients, siblings, and medical staff will need help in expressing feelings of anxiety, depression, guilt, and anger. Experienced professionals, including pediatric social workers, child psychologists and psychiatrists, child life specialists, and schoolteachers with special expertise in managing students with cancer should be called on by the pediatrician, pediatric oncologist, and nurses to assist when needed.

Chapter 486 - Principles of Treatment

Archie Bleyer

Treatment of children with cancer is one of the most complex endeavors in practice of pediatrics. It begins with an absolute requirement for the correct diagnosis (including subtype), proceeds through accurate and thorough staging of the extent of disease and determination of prognostic subgroup, provides appropriate multidisciplinary and usually multimodal therapy, and assiduously evaluates the possibilities of recurrent disease and of adverse late effects of the disease and the therapies rendered. Throughout treatment, every child with cancer should have the benefit of the expertise of specialized teams of providers of pediatric cancer care, including pediatric oncologists, pathologists, radiologists, surgeons, radiotherapists, nurses, and various support staff including nutritionists, social workers, psychologists, pharmacists, and other medical specialists.

The best chance for cure of cancer is during the initial course of treatment; the cure rates for patients with recurrent disease are much lower than those for patients with primary disease. All patients with cancer should be referred to an appropriate specialized center as soon as possible when the diagnosis of cancer is suspected. All such centers in North American are identified on the Children's Oncology Group Website (www.childrensoncologygroup.org) and on the National Cancer Institute cancer trials website (www.cancernet.nci.nih.gov). The remarkable increases in cure rates for childhood malignancies over the past 30 yr would not have occurred without the collective participation of patients and their physicians in clinical research programs at these centers. In the United States, the national organization of cancer clinical trials cooperative groups has been associated with a more than 80% reduction in the incidence of mortality due to cancer among children younger than 15 yr of age despite an overall increase in cancer incidence during this interval (Fig. 486–1). This remarkable achievement represents the effects of an effective multimodal, multi-institutional, multidisciplinary collaboration.

DIAGNOSIS AND STAGING

Accurate diagnosis and staging of the extent of disease is imperative, especially for children, whose cure rates are so high. Accuracy also is essential, not only because the nature of therapy depends strongly on the type of cancer but also because better and worse prognostic subgroups, based on stage of disease, have been established for most cancers that occur in children. Accordingly, children with a better prognosis

are treated with less intensive therapy, including lower doses of chemotherapy or radiotherapy, a shorter duration of treatment, or elimination of at least one treatment modality (e.g., radiotherapy, chemotherapy, or surgery). Accurate staging thus avoids the occurrence of excessive acute adverse effects and long-term complications of therapy in patients whose prognosis indicates

Figure 486-1 Reduction in the U.S. national cancer mortality rate among children younger than age 15 yr as a direct consequence of the National Cooperative Group Program sponsored by the National Cancer Institute. *Horizontal bars* indicate the duration of the existence of the national pediatric cancer cooperative groups, beginning with the Children's Cancer Group (CCG) in 1955. Other groups are the Pediatric Oncology Group (POG), which was derived from the Pediatric Divisions of the Southwest Oncology Group (SWOG) and the Cancer and Acute Leukemia Group B (CALGB), the National Wilms' Tumor Study Group (NWTSG), and the Intergroup Rhabdomyosarcoma Study Group (IRSG). *Solid triangles* represent the annual national mortality rate before age 15, and *solid circles* indicate the national cancer incidence rate before age 15 yr from the Surveillance, Epidemiology and End-Results (SEER) program of the National Cancer Institute. (Incidence and mortality data from Ries LAG, Eisner MP, Kosary CL, et al [editors]: *SEER Cancer Statistics Review, 1973–1999*. Bethesda, MD, National Cancer Institute, 2002. http://seer.cancer.gov/csr/1973_1999/)

that less therapy is required for cure. Overtreatment of patients with a more favorable prognosis is a definite risk if the patient is not referred to a cancer treatment center for management of adverse effects of such treatment. Conversely, undertreatment is also a clear risk if the diagnosis and stage are not correct, with the result being a compromise of an otherwise high potential for cure.

Diagnostic imaging is a critical phase of evaluation in most children with solid tumors (i.e., cancers other than leukemia). In the evaluation of children with cancer, MRI, CT, ultrasonography, scintigraphy (nuclear medicine scans), positron emission tomography, and spectroscopy, as appropriate, all serve a clear purpose, not only before treatment to determine the extent of disease and the appropriate therapy but also during follow-up to determine whether the therapy was effective. In addition, rapidity and completeness of response to treatment of an increasing number of malignant diseases in children are being evaluated and imaging techniques are used to quantify the magnitude of the response and to guide appropriate changes in the therapy if it is not adequate. Competence in the sedation of children for diagnostic imaging is also critical.

Expertise in pathology and laboratory medicine provides critical diagnostic support and guides therapy in most children with cancer. Fine-needle aspiration cytology avoids the need for open biopsies of masses in most locations of the body and can be performed in pediatric centers with appropriate expertise in diagnostic imaging, cytology, analgesia, and local anesthesia. Sentinel node mapping is increasingly being applied in the staging of children's cancers. The adequacy of surgery by evaluation of frozen sections of the surgical margins for tumor cells is essential in many tumor operations.

MULTIMODAL, MULTIDISCIPLINARY APPROACH

Many pediatric subspecialties are required to evaluate, treat, and manage children with cancer, including provision of primary modalities and multiple supportive care services (Fig. 486–2). Among the primary treatment modalities, more than two modalities are frequently used, with chemotherapy being the most widely used, followed, in order of use, by surgery, radiotherapy, and biologic agent therapy (Fig. 486–3).

The leukemias that occur in childhood are generally managed with chemotherapy alone, with a minor proportion of patients receiving cranial or craniospinal radiotherapy for prevention or treatment of overt central nervous system leukemia. Most children with non-Hodgkin lymphoma also are treated with chemotherapy alone. Exceptions include bulky nonlymphoblastic non-Hodgkin tumors, for which radiotherapy is often beneficial,

Figure 486-2 Multidisciplinary care of children with cancer. *Inner circle* designates primary modalities, and *outer ring* identifies supportive care elements to which all children with cancer have access.

and resectable primary Burkitt tumor in the abdomen, for which surgery is usually therapeutic. Localized therapy with surgery or irradiation or both is an important component of treatment of most solid tumors, including Hodgkin disease, but systemic multiagent chemotherapy is usually necessary because tumor dissemination is generally present even if undetectable. Chemotherapy alone is usually insufficient to eradicate gross residual tumors. Hence, children with malignant tumors not infrequently require treatment with all three modalities (see Fig. 486–3). Unfortunately, most treatments effective in children with cancer have a narrow therapeutic index (i.e., a low ratio of efficacy to toxicity). The acute and chronic adverse effects of these treatments can be minimized but not entirely avoided.

Over the past 10 yr, biologic agent therapy has become an important modality in a few childhood cancers (see Fig. 486–3). This type of treatment generally refers to immunotherapy, biologic response modifiers, or endogenously occurring molecules that in supraphysiologic doses have therapeutic effects. Examples are retinoic acid therapy in acute progranulocytic leukemia, monoclonal antibody therapy for certain non-Hodgkin lymphomas, imatinib mesylate for chronic myelogenous and Philadelphia chromosome–positive leukemias, and radioactive meta-iodobenzylguanidine (MIBG) therapy for neuroblastoma.

Chemotherapy is more widely used in children than in adults because children better tolerate the acute adverse effects and, in general, have malignant diseases that are more responsive to chemotherapy than are malignant diseases of adults. In general, radiotherapy is used sparingly in children because they are more vulnerable than adults to its late adverse effects.

Whenever possible, treatment is given on an outpatient basis. Children should remain living at home and in school as much as possible throughout treatment. Increasingly, pediatric cancer therapies are being administered to ambulatory patients, with the advent of such innovations as programmable infusion pumps, oral chemotherapeutic regimens, early discharge from hospital with intensive outpatient supportive care, and home health care services. Some patients miss a considerable amount of school in the 1st year after diagnosis owing to the intensity of therapy or its adverse effects and to the ensuing complications of the disease or therapy. Tutoring should be encouraged so that children do not fall behind in their schooling;

counseling should be provided as appropriate. In-hospital school services should be provided for those patients who must spend much of their time as inpatients receiving therapy for disease or for managing adverse effects.

Development of selective, highly effective therapy for cancer both in children and in adults is generally hindered by a lack of understanding of the molecular mechanisms that underlie malignant

Figure 486-3 The primary modalities of therapy used in the treatment of children with cancer. The relative sizes of the circles reflect the approximate proportion of the overall role in the management of pediatric cancer.

transformation. Also, de novo or acquired resistance to chemotherapy and radiotherapy remains an obstacle. Dramatic advances in the discipline have reduced the empiricism of therapy for cancer, but much remains unknown.

CHEMOTHERAPY

The most widely used modality in pediatric cancer therapy is chemotherapy (see Fig. 486–3). Moreover, therapy nearly always involves combinations of drugs, such as VAC (vincristine, doxorubicin [Adriamycin] or dactinomycin [Actinomycin D], and cyclophosphamide) and CHOP (cyclophosphamide, doxorubicin [Adriamycin], vincristine [Oncovin], and prednisone). Historically, sequential single-drug therapy rarely resulted in complete responses, and partial responses generally were infrequent and transient and grew progressively shorter in duration with each drug used. Combination chemotherapy became the standard when combinations of drugs with different mechanisms of action and nonoverlapping toxicities (e.g., POMP [mercaptopurine, vincristine (Oncovin), methotrexate, and prednisone], VAMP [vincristine, doxorubicin (Adriamycin), methotrexate, and prednisone], and MOPP [nitrogen mustard, vincristine (Oncovin), prednisone, and procarbazine] were first demonstrated to be effective in childhood leukemia. Most of the cytotoxic drugs for childhood cancer are selected from several classes of agents, including alkylating agents, antimetabolites, antibiotics, hormones, plant alkaloids, and topoisomerase inhibitors (Tables 486–1 and 486–2). The increased metabolic and cell cycle activity of malignant cells makes them more susceptible to the cytotoxic effects of these types of agents.

Because most antineoplastic agents are cell cycle dependent, their adverse effects are generally related to the proliferation kinetics of individual cell populations (Table 486–3). Most susceptible are those tissues or organs with high rates of cell turnover: bone marrow, oral and intestinal mucosa, epidermis,

**Includes high-dose chemotherapy with hematopoietic stem cell rescue.*

liver, and spermatogonia. The most common acute adverse effects are myelosuppression (with neutropenia and thrombocytopenia being the most problematic), immunosuppression, nausea and vomiting, hepatic dysfunction, upper and lower gastrointestinal mucositis, dermatitis, and alopecia. Fortunately, the tissues affected also recover relatively quickly such that the acute adverse effects are nearly always reversible. Life-threatening effects of many chemotherapy agents include severe neutropenia with infection, fungemia or fungal pneumonia due to immunosuppression, and septicemia, which is frequently contributed to by indwelling intravascular devices. Cardiomyopathy caused by anthracyclines (doxorubicin and daunorubicin) and renal failure from platinum-containing agents may also be life threatening and frequently disabling.

Least susceptible to chemotherapy and radiotherapy are cells that do not replicate or that replicate slowly, such as neurons, muscle cells, connective tissue, and bone. However, children are not exempt from toxicities of these tissues, probably because they are still undergoing proliferation, albeit at a slower pace than other tissues, during growth and growth spurts. Certain chemotherapeutic agents are particularly toxic to these tissues, and more so in adults than children; for instance, children are spared the neurotoxic effects of vincristine and methotrexate and the cardiotoxic effect of anthracyclines that occur in adults.

Children can in many ways physically endure the acute adverse effects of chemotherapy better than can adults. The maximum tolerated dose in children, when expressed on the basis of body surface area or body weight, is commonly greater than that in adults. A comparison of anticancer drugs tested in phase I trials in both adult and pediatric patients showed that the maximum tolerated dose in children was greater than that in adults for 70% of the agents, equal to that in adults for 15% of

the agents, and less than the adult dose for only 15% of the agents. For all the drugs that were compared, the mean pediatric maximum tolerated dose was greater than the adult mean.

Newer treatment approaches that have not reached general clinical application in children are specific tumor-directed therapies such as tumor antigen–specific monoclonal antibodies, tumor vaccines, antisense DNA and RNA transcripts, and antiangiogenic agents.

SURGERY

Superb pediatric surgical and anesthesia services are indispensable for children with cancer. The pediatric surgeon's role varies depending on the type of tumor. In children with solid tumors,

TABLE 486-3 -- Adverse Effects of Various Chemotherapeutic Agents

Drug	Common Adverse Effects	Uncommon Adverse Effects
Antimetabolites		
Methotrexate	Myelosuppression, mucositis, hepatitis, dermatitis	Neurotoxicity, osteoporosis, pneumonitis, cirrhosis
Cytarabine (Ara-C)	Myelosuppression, nausea and vomiting	Mucositis, hepatitis, neurotoxicity with intrathecal administration
6-Thioguanine	Myelosuppression	Nausea and vomiting
6-Mercaptopurine	Myelosuppression, nausea and vomiting, abdominal pain, hepatitis	Mucositis
5-Azacytidine	Nausea and vomiting, myelosuppression	Hepatitis
5-Fluorouracil	Myelosuppression, anorexia, nausea and vomiting, mucositis	Dermatitis, alopecia, hyperpigmentation, cerebellar ataxia
Alkylating Agents		
Cyclophosphamide, fosfamide	Myelosuppression, hemorrhagic cystitis, nausea and vomiting, alopecia	Mucositis, hyperpigmentation, hypo-osmolarity, infertility
Mechlorethamine (nitrogen mustard)	Nausea and vomiting, myelosuppression	Mucositis, alopecia
Chlorambucil	Myelosuppression	Nausea and vomiting, hepatitis
Melphalan	Myelosuppression	Anorexia, nausea and vomiting
Busulfan	Myelosuppression	Nausea and vomiting, alopecia, hyperpigmentation, pneumonitis
Antibiotics		
Doxorubicin, daunorubicin, idarubicin	Myelosuppression, nausea and vomiting, alopecia, mucositis	Cardiomyopathy
Dactinomycin (Actinomycin D)	Myelosuppression, nausea and vomiting, mucositis, alopecia	Dermatitis, hyperpigmentation, radiation recall
Bleomycin	Nausea and vomiting, dermatitis, hyperpigmentation, alopecia	Pulmonary fibrosis, mucositis, hypersensitivity reactions
Vinca Alkaloids		
Vincristine	Peripheral neuropathy, jaw pain, constipation, alopecia	Obstipation, cranial nerve palsies, seizures, myelosuppression, hemolysis, hypo-osmolarity
Vinblastine	Myelosuppression, nausea and vomiting, mucositis	Peripheral neuropathy, alopecia
Miscellaneous Agents		
Corticosteroids	Cushing's syndrome, diabetes, hypertension, growth delay	Hypokalemia, myopathy, osteoporosis, psychosis, adrenal insufficiency
Lomustine/carmustine (CCNU/BCNU)	Nausea and vomiting, delayed immunosuppression, myelosuppression	Hepatitis, stomatitis
Dacarbazine (DTIC)	Myelosuppression, nausea and vomiting, stomatitis	Hepatitis, alopecia
Procarbazine	Nausea and vomiting, myelosuppression, lethargy, dermatitis	Stomatitis, peripheral neuropathy, seizures, myopathy/myalgias
L-Asparaginase	Hypersensitivity reactions, coagulopathy, hyperglycemia, hepatic dysfunction	Encephalopathy, pancreatitis, abdominal pain

Cisplatin	Nausea and vomiting, nephrotoxicity, ototoxicity	Myelosuppression, seizures, peripheral and autonomic neuropathy
Hydroxyurea	Myelosuppression	Nausea and vomiting, mucositis, dermatitis, alopecia
Etoposide (VP-16)	Myelosuppression, nausea and vomiting	Hypersensitivity reactions, hypotension

complete resection with documented evidence of negative margins is often required for cure or long-term control. Considerable prolongation of life nearly always depends on whether the tumor is resectable and on the actual extent of resection.

With the exception of brainstem tumors and retinoblastoma, all solid tumors in children require a tissue diagnosis; therefore, biopsy of the suspected neoplasm is paramount. Staging with sentinel node biopsies has become a standard of care for several pediatric malignancies. Surgical expertise is essential for implantation of vascular access devices and removal and replacement of such devices when infection or thrombosis supervenes (see Chapter 165).

Increasingly, minimally invasive endoscopic surgical techniques are being used when indicated and, if the patient's condition permits, for biopsy and resection of tumor, direct ascertainment of residual disease and assessment of response, lysis of adhesions, and splenectomy.

RADIOTHERAPY

Radiotherapy is used sparingly in children, who are more susceptible than are adults to the adverse delayed effects of ionizing radiation. With more focused beams, such as conformal radiotherapy (a technology in which the beam conforms to the shape of the tumor and thus maximizes the amount of normal tissue spared) and better sedation and immobilization techniques, radiotherapy is becoming more frequently applied in children. Acute adverse effects from radiotherapy are less severe than those from chemotherapy and depend entirely on which part of the body is irradiated and the means of administration. Dermatitis is the most common general adverse effect, because skin is always in the treatment field. Nausea and diarrhea are common subacute adverse effects with abdominal radiotherapy. Mucositis nearly always occurs to some extent whenever oral or intestinal mucosa is in the treatment volume. Somnolence is common with cranial irradiation. Alopecia occurs where hair is in the radiation port.

Most radiotherapy schedules require treatment 5 days/wk for 4–7 wk, depending on the dose needed to control the tumor and on the amount and nature of normal tissue in the field. Most adverse effects are not noted until the second half of the course of irradiation. Late effects may occur months to years after radiotherapy and usually are dose-limiting manifestations. The type of delayed toxicity also depends on the site of irradiation. Examples are impaired growth resulting from cranial or vertebral irradiation, endocrine dysfunction from midbrain irradiation, pulmonary or cardiac insufficiency from chest irradiation, strictures and adhesions from abdominal irradiation, and infertility from pelvic irradiation.

ACUTE ADVERSE EFFECTS AND SUPPORTIVE CARE

Adverse treatment effects that occur early in therapy include metabolic disorders, bone marrow suppression, and immunosuppression. Patients with a large tumor burden may have had substantial breakdown of tumor cells, which, in some cases, causes renal function impairment, owing to tubular precipitates of uric acid crystals. This effect occurs most often in patients with leukemia and lymphoma (particularly Burkitt lymphoma) but also can occur in cases of large solid tumors (e.g., hepatoblastoma,

germ cell tumors, and neuroblastoma). Before therapy is initiated, the serum levels of uric acid and creatinine should be measured and adequate hydration ensured; allopurinol (a xanthine oxidase inhibitor) can be given, if necessary, to lower uric acid levels to within the normal range. In the metabolic **tumor lysis syndrome,** phosphates and potassium are released into the circulation in large quantities as cells are lysed by treatment. Symptomatic hyperkalemia and hyperphosphatemia with subsequent hypocalcemia may develop in the setting of inadequate renal function.

Virtually all chemotherapy regimens can produce myelosuppression, as can tumors that invade and replace bone marrow. Anemia can be corrected by transfusions of packed erythrocytes, and thrombocytopenia, by platelet infusions. Patients receiving immunosuppressive therapy should receive irradiated blood products to prevent graft versus host disease. Granulocytopenia (granulocyte counts < 500/mm^3) poses a risk of life-threatening infection. Febrile granulocytopenic patients should be hospitalized and treated with empirical broad-spectrum intravenous antimicrobial therapy pending the results of appropriate cultures of blood, urine, or any obvious sites of infection (see Chapter 164). Treatment is continued until fever resolves and the granulocyte count rises. If fever persists more than 1 wk while the patient is receiving broad-spectrum antibiotics, the possibility of fungal infection must be considered. Fungal infections caused by *Candida* and *Aspergillus* are common in immunosuppressed patients. Opportunistic organisms such as *Pneumocystis carinii* can produce fatal pneumonia. Prophylactic treatment with trimethoprim/sulfamethoxazole is given when severe or prolonged immunosuppression is anticipated.

Viruses of low pathogenicity can produce serious disease in the setting of immunosuppression caused by malignancy or its treatment. Patients should not be given live virus vaccines. Children who are receiving chemotherapy and who are exposed to chickenpox should receive varicella-zoster immunoglobulin and, if clinical disease develops, should be hospitalized and treated with intravenous acyclovir.

Adequate pain management is critical. The World Health Organization (WHO) guidelines are particularly useful in the management of pain associated with cancer and cancer therapy (see Chapter 66).

It is common for patients undergoing cancer therapy to lose more than 10% of body weight. Patients sometimes reduce their food intake because of temporary, treatment-associated nausea, stomatitis, and vomiting. Appetite loss is not a cause for alarm. Malnutrition is a particular risk in patients receiving radiotherapy involving the abdomen or the head and neck, intensive chemotherapy, or total body irradiation and high-dose chemotherapy before marrow transplantation. If oral supplementation proves inadequate, such patients may require enteral tube feedings or parenteral hyperalimentation.

CHRONIC ADVERSE EFFECTS AND DELAYED SEQUELAE

Injury to tissues with low repair potential often results in long-lasting or permanent deficit. For example, anthracycline-induced cardiomyopathy usually produces refractory cardiac dysfunction, and the leukoencephalopathy caused by intrathecal methotrexate and by central nervous system radiotherapy is frequently only partially reversible.

Late consequences of therapy can cause substantial morbidity (Table 486–4). Successful surgical resection may result in loss of important functional structures. Irradiation can produce irreversible organ damage, with symptoms and functional limitations depending on the organ involved and the severity of the damage. Many radiotherapy-related problems do not become obvious until the patient is fully grown, such as asymmetry between irradiated and nonirradiated areas or extremities. Irradiation of fields that include endocrine organs can cause hypothyroidism, pituitary dysfunction, or infertility. In sufficient

TABLE 486-4 -- **Long-Term Sequelae of Cancer Therapy**

Sequela	**Causative Treatment**
Second cancers	Genetic predisposition, irradiation, alkylating agents
Sepsis	Splenectomy
Hepatotoxicity	Methotrexate, 6-mercaptopurine, irradiation
Amputation	Surgery for osteogenic sarcoma
Scoliosis	Irradiation, surgery
Osteonecrosis (hip)	Corticosteroids, methotrexate
Pulmonary dysfunction (interstitial fibrosis)	Irradiation, bleomycin, busulfan, nitrosourea
Cardiomyopathy	Doxorubicin, daunomycin, irradiation
Leukoencephalopathy	Cranial irradiation, methotrexate
Impaired cognition or intelligence	Cranial irradiation, methotrexate
Infertility	Alkylating agents, irradiation
Pituitary dysfunction	Cranial irradiation
Cataracts	Corticosteroids, cranial irradiation
Hypothyroidism	Neck irradiation

doses, cranial irradiation can produce neurologic dysfunction and spinal irradiation can produce growth retardation.

Chemotherapy also carries the risk of long-lasting organ damage. Of particular concern are leukoencephalopathy after high-dose methotrexate therapy; infertility in male patients treated with alkylating agents (e.g., cyclophosphamide); myocardial damage caused by anthracyclines; pulmonary fibrosis caused by bleomycin; pancreatitis caused by asparaginase; renal dysfunction due to ifosfamide, nitrosourea, or platinum agent; and hearing loss from cisplatin. Development of these sequelae may be dose related and is usually irreversible. Appropriate baseline and intermittent testing should be performed before these drugs are administered to ensure that there is no pre-existing damage to the organs likely to be affected and to permit monitoring of the effects of treatment-induced changes.

Perhaps the most serious late effect is the occurrence of second cancers in patients successfully cured of a first malignancy. The risk appears to be cumulative, increasing by about 0.5% per year, resulting in approximately a 12% incidence at 25 years after treatment. Patients who have been treated for childhood cancer should be examined annually, with particular attention to possible late effects of therapy, including second malignancies.

PALLIATIVE CARE

At all stages of caring for children with cancer, principles of palliative care should be applied to relieve pain and suffering and to provide comfort (see Chapter 38). Pain is a serious cause of suffering among patients with cancer and may be the result of organ obstruction or compression or bone metastasis or may be neuropathic. Pain should be managed in a stepwise manner, as recommended by the WHO, in accordance with the principles of selecting the appropriate analgesic, prescribing the appropriate dosage, administering the drug by the appropriate route, and choosing

an appropriate dosing schedule to prevent persistent pain and to relieve breakthrough pain (see Chapter 66). In addition, the dosage should be aggressively titrated while attempts are made to prevent, anticipate, and manage side effects. Adjuvant drugs and sequential trials of analgesic drugs should be considered.

The goals in the care of dying patients are to avoid distress for the patient, family, and caregivers; to provide care consistent with the patient's and family's wishes; and to comply with and advocate for clinical, cultural, and ethical standards.

Chapter 487 - The Leukemias

David G. Tubergen
Archie Bleyer

The leukemias are the most common malignant neoplasms in childhood, accounting for about 41% of all malignancies that occur in children younger than 15 yr of age. In 2000, approximately 3,600 children were diagnosed with leukemia in the United States, for an annual incidence of 4.1 new cases per 100,000 children younger than 15 yr of age. Acute lymphoblastic leukemia (ALL) accounts for about 77% of cases of childhood leukemia, acute myelogenous leukemia (AML) for about 11%, chronic myelogenous leukemia (CML) for 2–3%, and juvenile chronic myelogenous leukemia (JCML) for 1–2%. The remaining 7–9% of cases include a variety of acute and chronic leukemias that do not fit classic definitions for ALL, AML, CML, or JCML.

The leukemias may be defined as a group of malignant diseases in which genetic abnormalities in a hematopoietic cell give rise to a clonal proliferation of cells. The progeny of these cells have a growth advantage over normal cellular elements owing to an increased rate of proliferation, a decreased rate of spontaneous apoptosis, or both. The result is a disruption of normal marrow function and, ultimately, marrow failure. The clinical features, laboratory findings, and responses to therapy vary depending on the type of leukemia.

487.1 Acute Lymphoblastic Leukemia

Childhood ALL was the first disseminated cancer shown to be curable and as such has represented the model malignancy for the principles of cancer diagnosis, prognosis, and treatment. It is actually a heterogeneous group of malignancies with a number of distinctive genetic abnormalities that result in varying clinical behaviors and responses to therapy.

Epidemiology.

Approximately 2,800 children are diagnosed with ALL in the United States annually. It has a striking peak incidence between 2–6 yr of age and occurs slightly more frequently in boys than in girls. This peak age incidence was apparent decades ago in white populations in advanced socioeconomic countries, but more recently has also been confirmed in the black population of the United States. The disease is more common in children with certain chromosomal abnormalities such as Down syndrome, Bloom syndrome, ataxia-telangiectasia, and Fanconi syndrome. Among identical twins, the risk to the second twin if one develops leukemia is greater than that in the general population. The risk may be as high as 100% if the first twin is diagnosed during the first year of life and the twins shared the same (monochorionic) placenta. If the first twin develops ALL by 5–7 yr of age, the risk to the second twin is at least twice that in the general population, regardless of zygosity.

Etiology.

In virtually all cases, the etiology of ALL is unknown, although several genetic and environmental factors are associated with childhood leukemia (Box 487–1). Exposure to medical diagnostic radiation both in utero and in childhood has been associated with an increased incidence of ALL. In addition, published descriptions and investigations of geographic clusters of cases have raised concern that environmental factors may increase the incidence of ALL. Thus far, no such factors other than radiation have been identified, except for an association between B-cell ALL and Epstein-Barr viral infections in certain developing countries.

Pathogenesis.

The classification of ALL depends on characterizing the malignant cells in the bone marrow to determine the morphology, phenotypic characteristics as measured by cell membrane markers, and cytogenetic and molecular genetic features. Morphology alone is usually adequate to establish a diagnosis, but the other studies are essential for disease classification, which may have a major influence on both the prognosis and the choice of appropriate therapy. In terms of clinical significance, the most important distinguishing morphologic feature is the French-American-British (FAB) L3 subtype, which is evidence of a mature B-cell leukemia. The L3 type, also known as Burkitt leukemia, is one of the most rapidly growing cancers in humans and requires a different therapeutic approach. Phenotypically, surface markers show that about 85% of cases of ALL are derived from progenitors of B cells, about 15% are derived from T cells, and about 1% are derived from B cells. A small percentage of children diagnosed with leukemia have a disease characterized by surface markers of both lymphoid and myeloid derivation.

Chromosomal abnormalities are found in most patients with ALL (Table 487–1). The abnormalities, which may be related to chromosomal number, translocations, or deletions, provide important prognostic information. Specific chromosomal findings, such as the t(9;22) translocation, suggest a need for additional, molecular genetic studies. The polymerase chain reaction and fluorescence in situ hybridization techniques, for example, offer the ability to pinpoint molecular genetic abnormalities and to detect small numbers of malignant cells during follow-up; however, the clinical utility of these findings has yet to be firmly established.

Clinical Manifestations.

The initial presentation of ALL is usually nonspecific and relatively brief. Anorexia, fatigue, and irritability are often present, as is an intermittent, low-grade fever. Bone or joint pain, particularly in the lower extremities, may be present. Patients often have a history of an upper respiratory tract infection in the proceeding 1–2 mo. Less

commonly, symptoms

ALL = acute lymphoblastic leukemia; AML = acute myelogenous leukemia.

**Per the French-American-British classification of acute myelogenousleukemia (see Table 487–2).*

may be of several months' duration, may be predominantly localized to the bones or joints, and may include joint swelling. As the disease progresses, signs and symptoms of bone marrow failure become more obvious with the occurrence of pallor, fatigue, bruising, or epistaxis, as well as fever, which may be caused by infection.

On physical examination, findings of pallor, listlessness, purpuric and petechial skin lesions, or mucous membrane hemorrhage may reflect bone marrow failure. The proliferative nature of the disease may be manifested as lymphadenopathy, splenomegaly, or, less commonly, hepatomegaly. In patients with bone or joint pain, there may be exquisite tenderness on bone palpation or objective evidence of joint swelling and effusion. Rarely, patients show signs of increased intracranial pressure that indicate leukemic involvement of the central nervous system (CNS). These include papilledema (see Fig. 485–5), retinal hemorrhages, and cranial nerve palsies. Respiratory distress is usually related to anemia but may occur in patients with an obstructive airway problem, owing to a large mediastinal mass of lymphoblasts. This problem is most typically seen in adolescent boys with T-cell ALL.

Diagnosis.

The diagnosis of ALL is strongly suggested by peripheral blood findings indicative of bone marrow failure. Anemia and thrombocytopenia are seen in most patients. Leukemic cells are often not observed in the peripheral blood in routine laboratory examinations. Most patients with ALL present with total leukocyte counts of less than 10,000/µL. In such cases, the leukemic cells are often initially reported to be atypical lymphocytes, and it is only with further evaluation that the cells are found to be part of a malignant clone. When the results of an analysis of peripheral blood suggest the possibility of leukemia, a bone marrow examination should be done promptly to establish the diagnosis. Bone marrow aspiration alone is usually sufficient, but sometimes a bone marrow biopsy is needed to provide adequate tissue for study or to exclude other possible causes of bone marrow failure.

ALL is diagnosed by a bone marrow evaluation that demonstrates more than 25% of the bone marrow cells as a homogeneous population of lymphoblasts. Staging of ALL is partly based on a cerebrospinal fluid (CSF) examination. If lymphoblasts are found and the CSF leukocyte count is elevated, overt CNS (or meningeal) leukemia is present; a worse stage is implied and additional CNS and systemic therapies are indicated. The staging lumbar puncture may be performed in conjunction with the first dose of intrathecal chemotherapy if the diagnosis of leukemia has been previously established from bone marrow evaluation.

DIFFERENTIAL DIAGNOSIS.

Acute lymphoblastic leukemia must be differentiated from acute myelogenous leukemia (AML); other malignant diseases that may invade the bone marrow and cause marrow failure such as neuroblastoma, rhabdomyosarcoma, Ewing's sarcoma, and retinoblastoma; and causes of primary bone marrow failure, such as aplastic anemia (either congenital or acquired) and myelofibrosis. Failure of a single cell line, as in transient erythroblastic anemia, immune thrombocytopenia, and congenital or acquired neutropenia, sometimes produces a clinical picture that is difficult to distinguish from ALL and that may require bone marrow examination. A high index of suspicion is required to differentiate ALL from infectious mononucleosis in patients with acute onset of fever and lymphadenopathy and from rheumatoid arthritis in patients with fever and joint swelling. These presentations also may require bone marrow examination.

Treatment.

The single most important prognostic factor in ALL is the treatment: without effective therapy the disease is fatal. The survival rates of children with ALL over the past 40 yr have improved as the results of clinical trials have improved the therapies and outcomes (Fig. 487–1).

The choice of treatment of ALL is based on the estimated clinical risk of relapse in the patient, which varies widely among the subtypes of ALL. Three of the most important predictive factors are the age of the patient at the time of diagnosis, the initial leukocyte count, and the speed of response to treatment (i.e., how rapidly the blast cells can be cleared from the marrow or peripheral blood). Different study groups use various factors to define risk, but a patient between 1–10 yr of age and with a leukocyte count of less than 50,000/µL is widely used to define average

Figure 487.1-1 Survival rates of children with acute lymphoblastic leukemia treated on sequential Children's Cancer Group (COG) clinical trials over 30 yr. (Data provided by H. N. Sather.)

risk. Patients considered to be at higher risk are children who are older than 10 yr of age or who have an initial leukocyte count of more than 50,000/µL. Recent trials have shown that the outcome for patients at higher risk can be improved by administration of more intensive therapy despite the greater toxicity of such therapy. Infants with ALL, along with patients who present with specific chromosomal abnormalities such as t(9;22) or t(4;11), have an even higher risk of relapse despite intensive therapy. Clinical trials have also demonstrated that the prognosis for patients with a slower response to initial therapy may be improved by therapy that is more intensive than the therapy considered necessary for patients who respond more rapidly.

Most children with ALL are treated on clinical trials conducted by national or international cooperative groups. In general, the initial therapy is designed to eradicate the leukemic cells from the bone marrow and is known as **remission induction.** During this phase, therapy is usually given for 4 wk and consists of vincristine weekly, a corticosteroid such as dexamethasone or prednisone, and either repeated doses of native L-asparaginase or a single dose of a long-acting asparaginase preparation. Intrathecal cytarabine or methotrexate, or both, may also be given. Patients at higher risk also receive daunomycin at weekly intervals. With this approach, 98% of patients are in remission, as defined by less than 5% blasts in the marrow and a return of neutrophil and platelet counts to near-normal levels after 4–5 wk of treatment. Intrathecal chemotherapy is usually given at the time of diagnosis and once more during induction.

The second phase of treatment focuses on **CNS therapy** in an effort to prevent later CNS relapses. Intrathecal chemotherapy is given repeatedly by lumbar puncture in conjunction with intensive systemic chemotherapy. The likelihood of later CNS relapse is thereby reduced to less than 5%. A small proportion of patients with

features that predict a high risk of CNS relapse receive irradiation to the brain and spinal cord. This includes those patients who have lymphoblasts in the CSF and an elevated CSF leukocyte count at the time of diagnosis.

After remission induction, many regimens provide 14–28 wk of multiagent therapy, with the drugs and schedules used varying depending on the risk group of the patient. Finally, patients are given daily mercaptopurine and weekly methotrexate, usually with intermittent doses of vincristine and a corticosteroid. This period, known as the **maintenance phase** of therapy, lasts for 2–3 yr, depending on the protocol used. A small number of patients with particularly poor prognostic features, principally those with the t(9;22) translocation known as the Philadelphia chromosome, may undergo bone marrow transplantation during the first remission. In ALL, this chromosome is similar but not identical to the Philadelphia chromosome of chronic myelogenous leukemia (CML).

The major impediment to a successful outcome is relapse of the disease. Relapse occurs in the bone marrow in 15–20% of patients with ALL and carries the most serious implications, especially if it occurs during or shortly after completion of therapy. Intensive chemotherapy with agents not previously used in the patient followed by allogeneic stem cell transplantation can result in long-term survival for a few patients with bone marrow relapse (see Chapter 125).

Patients with relapse in the CNS usually present with signs and symptoms of increased intracranial pressure and may present with isolated cranial nerve palsies. The diagnosis is confirmed most readily by demonstrating the presence of leukemic cells in the CSF and, rarely, by imaging studies. The treatment includes intrathecal medication and craniospinal irradiation. Systemic chemotherapy must also be used because these patients are at high risk for subsequent bone marrow relapse. Most patients with leukemic relapse confined to the CNS do well, especially those in whom the CNS relapse occurs after chemotherapy has been completed or during the latter phase of chemotherapy.

Testicular relapse occurs in 1–2% of boys with ALL, usually after completion of therapy. Such relapse presents as painless swelling of one or both testes. The diagnosis is confirmed by biopsy of the affected testis. Treatment includes systemic chemotherapy and local irradiation. A high proportion of boys with a testicular relapse can be successfully re-treated, and the survival rate of these patients is good.

SUPPORTIVE CARE.

Close attention to the medical supportive care needs of the patients is essential in successfully administering aggressive chemotherapeutic programs. Patients with a large tumor burden are prone to tumor lysis syndrome as therapy is initiated. Chemotherapy often produces severe myelosuppression, which may require erythrocyte and platelet transfusion and which always requires a high index of suspicion and aggressive empirical antimicrobial therapy for sepsis in febrile children with neutropenia. Patients need to receive prophylactic treatment of *Pneumocystis carinii* pneumonia during chemotherapy and for several months after completing treatment.

The success of therapy has changed ALL from an acute disease with a high mortality rate to a chronic disease. However, such chronic treatment can incur substantial academic, developmental, and psychosocial costs for children with ALL and considerable financial costs and stress for their families. Because of the intensity of therapy, long-term and acute toxicity effects may occur. An array of cancer care professionals with training and experience in addressing the myriad of problems that may arise is essential to minimize the complications and achieve an optimal outcome.

Prognosis.

Most children with ALL can now be expected to have long-term survival, with the rate greater than 80% after 5 yr (see Fig. 487–1). The most important prognostic factor is the choice of appropriate risk-directed therapy, with the type of treatment chosen according to the type of ALL, the stage of disease, the age of the patient, and the rate of response to initial therapy. Characteristics generally believed to adversely affect outcome include an age younger than 1 yr or older than 10 yr at diagnosis, a leukocyte count of more than 100,000/µL at diagnosis, or a slow response to initial therapy. Chromosomal abnormalities, including hypodiploidy, the Philadelphia chromosome, and t(4;l1), portend a poorer outcome. More favorable characteristics include a rapid response to therapy, hyperdiploidy, and rearrangements of the *TEL/AML1* genes.

487.2 Acute Myelogenous Leukemia

Epidemiology.

AML comprises 11% of the cases of leukemia in childhood in the United States, with approximately 380 children diagnosed with AML annually. One subtype, acute promyelocytic leukemia (APL), is more common in certain other regions of the world, but incidence of the other types is generally uniform. Several chromosomal abnormalities associated with AML are identified, but no predisposing genetic or environmental factors can be identified in most patients (see Table 487–1).

Pathogenesis.

The characteristic feature of AML is more than 30% of bone marrow cells on bone marrow aspiration or biopsy touch preparations that constitute a rather homogeneous population of blasts cells with features similar to those that characterize early differentiation states of the myeloid-monocyte-megakaryocyte series of blood cells. The most common classification of the subtypes of AML is the FAB system (Table 487–2). Although this system is based on morphologic criteria alone, current practice also requires the use of flow cytometry for identification of cell surface antigens and of chromosomal and molecular genetic techniques for additional diagnostic precision and also to aid the choice of therapy.

TABLE 487.2-2 -- **French-American-British (FAB) Classification of Acute Myelogenous Leukemia**

Subtype	Common Name
M1	Acute myeloblastic leukemia without maturation
M2	Acute myeloblastic leukemia with maturation
M3	Acute promyeloblastic leukemia
M4	Acute myelomonocytic leukemia
M5	Acute monocytic leukemia
M6	Erythroleukemia
M7	Acute megakaryocytic leukemia

Clinical Manifestations.

The production of symptoms and signs of AML, as in ALL, is due to replacement of bone marrow by malignant cells and to secondary bone marrow failure. Thus, patients with AML may present with any or all of the findings associated with marrow failure in ALL. In addition, patients with AML present with signs and symptoms that infrequently occur with ALL, including subcutaneous nodules or “blueberry muffin” lesions, infiltration of the gingiva, signs and laboratory findings of disseminated intravascular coagulation (especially indicative of acute promyelocytic leukemia), and discrete masses, known as **chloromas** or **granulocytic sarcomas.** These masses may occur in the absence of apparent bone marrow involvement and are typically associated with the M2 subcategory of AML with a t(8;21) translocation.

Diagnosis.

Analysis of bone marrow aspiration and biopsy specimens of patients with AML typically reveals the features of a hypercellular marrow consisting of a rather monotonous pattern of cells with features that permit FAB subclassification of disease. Special stains assist in identification of myeloperoxidase-containing cells, thus confirming both the myelogenous origin of the leukemia and the diagnosis. Some chromosomal abnormalities and molecular genetic markers are characteristic of specific subtypes of disease (see Box 487–1).

Treatment.

Aggressive multiagent chemotherapy is successful in inducing remission in about 80% of patients. Up to 10% of patients die of either infection or bleeding before a remission can be achieved. Matched-sibling bone marrow or stem cell transplantation after remission has been shown to achieve long-term disease-free survival in 60–70% of patients. Continued chemotherapy for patients who do not have a matched donor is less effective than marrow transplantation but nevertheless is curative in some patients.

Acute promyelocytic leukemia, characterized by a gene rearrangement involving the retinoic acid receptor, is very responsive to retinoic acid combined with anthracyclines. The success of this therapy makes marrow transplantation in first remission unnecessary for patients with this disease.

The supportive care needs of patients with AML are basically the same as those given for ALL. The very intensive therapy required in AML produces prolonged bone

marrow suppression with a very high incidence of serious infections.

487.3 Down Syndrome and Acute Leukemia and Myeloproliferation

Acute leukemia occurs about 14 times more frequently in children with Down syndrome than in the general population. The ratio of ALL to AML in patients with Down syndrome is the same as that in the general population. In Down children with ALL, the expected outcome of treatment is the same as that for other children. However, patients with Down syndrome demonstrate a remarkable sensitivity to methotrexate and other antimetabolites, which can result in substantial toxicity if standard doses are administered. In AML, however, patients with Down syndrome have much better outcomes, with a greater than 80% long-term survival rate, than does the non-Down syndrome population. After induction therapy, these patients require less intensive therapy to achieve the better results.

Neonates with Down syndrome are prone to develop a transient leukemia or myeloproliferative syndrome characterized by high leukocyte counts, blast cells in the peripheral blood, and associated anemia, thrombocytopenia, and hepatosplenomegaly. These features usually resolve within days to a few weeks after onset. Although these neonates may require temporary transfusion support, they do not require chemotherapy. However, patients who have Down syndrome and who develop this transient leukemia or myeloproliferative syndrome require close follow-up because 20–30% will develop typical leukemia within the first few years of life.

487.4 Chronic Myelogenous Leukemia

CML is a clonal disorder of the hematopoietic tissue that accounts for 2–3% of all cases of childhood leukemia. About 99% of the cases are characterized by a specific translocation, t(9;22)(q34;q11), known as the **Philadelphia chromosome.** The disease has been associated with exposure to ionizing radiation but very few children with CML have a history of such exposure. The disease is characterized clinically by an initial chronic phase in which the malignant clone produces an elevated leukocyte count with a predominance of mature forms but with increased numbers of immature granulocytes. The spleen is often greatly enlarged, often resulting in pain in the left upper quadrant of the abdomen. In addition to leukocytosis, the blood counts may reveal mild anemia and thrombocytosis.

Typically, the chronic phase terminates 3–4 yr after onset when the CML moves into the accelerated or “blast crisis” phase. At this point, the blood counts rise dramatically and cannot be controlled with drugs such as hydroxyurea. Additional manifestations may occur, including hyperuricemia and neurologic symptoms, which are related to increased blood viscosity with decreased CNS perfusion.

The presenting symptoms of CML are entirely nonspecific and may include fever, fatigue, weight loss, and anorexia. Splenomegaly may also be present. The diagnosis is suggested by increased numbers of myeloid cells with differentiation to mature forms in the peripheral blood and bone marrow and is confirmed by cytogenetic studies that demonstrate the presence of the characteristic Philadelphia chromosome. Molecular techniques usually demonstrate the *BCR-ABL* gene rearrangement. The translocation, although characteristic of CML, is also found in a small percentage of patients with ALL or AML.

The signs and symptoms of CML in the chronic phase can be controlled with hydroxyurea, which will gradually return the leukocyte count to normal. However, this treatment is not definitive and does not eliminate the abnormal clone or prevent progression of the disease. Therapy with interferon-a produces hematologic remission in up to 70% of patients and cytogenetic remission in about 20% of patients. Combination chemotherapy has been successful in achieving remission in a small proportion of patients with CML; however, the optimum therapy is allogeneic bone marrow or stem cell transplantation from an HLA-matched sibling, which is curative in up to 80% of children.

Exciting results have recently been reported with imatinib mesylate, an agent designed specifically to inhibit the *BCR-ABL* tyrosine kinase. Although this drug is very effective in adult patients, trials in children are just beginning. It is hoped that this agent will usher in a new era of therapy for CML by specifically targeting the genetic abnormality of the malignant clone of cells.

487.5 Juvenile Chronic Myelogenous Leukemia

Juvenile chronic myelogenous leukemia (JCML), also known as juvenile myelomonocytic leukemia, is a clonal proliferation of hematopoietic stem cells that typically affects children younger than 2 yr of age. Patients with this disease do not have the Philadelphia chromosome that is characteristic of CML. Patients with JCML present with rashes, lymphadenopathy, and splenomegaly. Analysis of the peripheral blood often shows an elevated leukocyte count and may also show thrombocytopenia and the presence of erythroblasts. The bone marrow shows a myelodysplastic pattern, with blasts accounting for less than 30% of cells. No distinctive cytogenetic abnormalities are seen. JCML is rare constituting less than 2% of all cases of childhood leukemia. Therapeutic reports are largely anecdotal. Patients with neurofibromatosis have a predilection for this type of leukemia. Stem cell transplantation offers the best opportunity for cure, but much less so than for classic CML.

487.6 Infant Leukemia

Only about 2% of cases of leukemia during childhood occur before the age of 1 yr. Several unique biologic features and a particularly poor prognosis are characteristic of ALL during infancy. More than two thirds of the cases demonstrate rearrangements of the *MLL* gene, classically a translocation involving the q23 band of chromosome 11, and it is this subset of patients that largely accounts for the very high relapse rate. These patients often present with hyperleukocytosis and extensive tissue invasion, including CNS disease. Subcutaneous nodules **(leukemia cutis)** and tachypnea due to diffuse pulmonary infiltration by leukemic cells are more frequently observed in infants than in older children. The leukemic cell morphology is usually that of large irregular lymphoblasts (FAB L2) with a phenotype negative for the CD10 (cALLa) marker.

Very intensive chemotherapy programs including stem cell transplantation are being explored in infants with rearrangement of *MLL* in band 11q23, but none has yet proved satisfactory. Infants with leukemia who lack the 11q23 rearrangements have a prognosis similar to that of older children with ALL. Infants with AML often present with CNS or skin involvement and have the FAB M4 subtype, which is commonly known as **acute myelomonocytic leukemia.** The treatment may be the same as that for older children with AML. Meticulous supportive care is necessary because of the young age and aggressive therapy needed in these patients.

Chapter 488 - Lymphoma

Gerald S. Gilchrist

Lymphoma is the third most common cancer in children in the United States, with an annual incidence of 13–14 per million children. The two broad categories of lymphoma, Hodgkin disease and non-Hodgkin lymphoma (NHL), have such different clinical manifestations and treatments that they are considered separately.

488.1 Hodgkin Disease

Epidemiology.

In the United States, Hodgkin disease accounts for about 5% of cancers in persons younger than 15 yr of age and for about 15% in persons 15–19 yr of age, with an incidence ratio among blacks and whites of 1.6. In industrialized countries the highest rate is in adolescents and young adults, in contrast to developing countries, where the highest rate is in younger children.

Three forms of Hodgkin disease have been identified in epidemiologic studies: a childhood form (= 14 yr of age), a young adult form (15–34 yr of age), and an older adult form (55–74 yr of age). The epidemiologic similarities of Hodgkin disease in young adults to paralytic polio in the pre-vaccine era suggest an infectious cause. The role of Epstein-Barr virus (EBV) is supported by serologic studies and the frequent presence of EBV genome in biopsy material. Males predominate in patients younger than 10 yr of age at diagnosis, with roughly equal gender incidence in adolescence. Pre-existing immunodeficiency, either congenital or acquired, increases the risk of developing Hodgkin disease. A genetic predisposition or a common exposure to the same etiologic agent could account for an apparent increased risk in twins and first-degree relatives ranging from 3- to 7-fold.

Pathogenesis.

The **Reed-Sternberg cell,** a large cell (15–45?µm in diameter) with multiple or multilobulated nuclei, is considered the hallmark of Hodgkin disease, although similar cells are seen in infectious mononucleosis, NHL, and other conditions. There is now general agreement that the Reed-Sternberg cell arises from germinal center B-cells in most cases. An infiltrate of

apparently normal lymphocytes, plasma cells, and eosinophils surround the Reed-Sternberg cell and varies with the histologic subtype. Other features that distinguish the histologic subtypes include various degrees of fibrosis and the presence of collagen bands, necrosis, or malignant reticular cells. The four major histologic subtypes are **lymphocyte predominant, nodular sclerosing, mixed cellularity, and lymphocyte depleted.** More recently, additional immunohistochemically identifiable subtypes have been described but their prognostic or therapeutic significance is not yet apparent in pediatric patients. Most cases previously classified as lymphocyte depleted are now considered to represent high-grade non-Hodgkin lymphoma. Since the advent of curative therapy, the prognostic significance of histologic subtype has been virtually eliminated.

Hodgkin disease appears to arise in lymphoid tissue and spreads to adjacent lymph node areas in a relatively orderly fashion. Hematogenous spread also occurs, leading to involvement of the liver, spleen, bone, bone marrow, or brain, and is usually associated with systemic symptoms. Levels of various cytokines have been shown to be elevated in patient sera or are produced by cultured cell lines or Hodgkin disease tissue. They may well be responsible for the systemic symptoms of fever and night sweats (interleukin 1 or 2) and weight loss (tissue necrosis factor [TNF]), in addition to influencing the proliferation of Reed-Sternberg cells and inducing immunosuppression (transforming growth factor-ß)

Various degrees of cellular immune impairment can be identified in the majority of newly diagnosed cases of Hodgkin disease. The severity of the immune defect varies with the extent of disease and persists even after successful curative therapy. Whether it predisposes to the disease or results from it is unknown.

Clinical Manifestations.

Painless, firm, cervical, or supraclavicular lymphadenopathy is the most common presenting sign. Inguinal or axillary lymphadenopathy sites are uncommon areas of presentation. An anterior mediastinal mass is often present and can rapidly disappear with therapy (Fig. 488–1). Clinically detectable hepatosplenomegaly is rarely encountered. Depending on the extent and location of nodal and extranodal disease, patients might present with symptoms and signs of airway obstruction, pleural or pericardial effusion, hepatocellular

Figure 488.1-1 *A*, Anterior mediastinal mass in a patient with Hodgkin disease before therapy. *B*, Complete disappearance of mediastinal mass in the same patient after 2 mo of chemotherapy.

dysfunction, or bone marrow infiltration (anemia, neutropenia, or thrombocytopenia). Nephrotic syndrome is a rare but recognized presenting manifestation of Hodgkin disease.

Systemic symptoms considered important in staging are unexplained fever, weight

loss, or drenching night sweats. Less common and not considered of prognostic significance are symptoms of pruritus, lethargy, anorexia, or pain that worsens after ingestion of alcohol.

Because of the impaired cellular immunity, concomitant tuberculous or fungal infections may complicate Hodgkin disease and predispose to complications during immunosuppressive therapy. In the pre-vaccine era varicella-zoster infections occurred at some time during the course of the disease in about 30% of cases.

Diagnosis.

Any patient with persistent, unexplained lymphadenopathy unassociated with an obvious underlying inflammatory or infectious process should have a chest radiograph to identify the presence of a mediastinal mass before undergoing node biopsy. Unless signs or symptoms dictate otherwise, additional laboratory studies can be delayed until the biopsy results are available. Patients with persistently enlarged lymph nodes, even after serologically proven infectious mononucleosis, should also be considered for biopsy.

Formal excisional biopsy is preferred over needle biopsy to ensure that adequate tissue is obtained, both for light microscopy and for appropriate immunocytochemical and molecular studies, culture, and cytogenetic analysis if routine studies fail to provide a firm diagnosis. Hodgkin disease is rarely diagnosed with certainty on frozen section. Ideally, a portion of the biopsy specimen should be frozen and stored to allow for additional studies.

Once the diagnosis of Hodgkin disease is established, extent of disease (i.e., stage) should be determined. These studies should provide all the information needed to clinically stage the disease based on the Ann Arbor classification (Boxes 488–1 (Box Not Available) and 488–2). A complete blood cell count (CBC) identifies abnormalities that might suggest marrow involvement. Erythrocyte sedimentation rate (ESR), serum copper determination, and serum ferritin levels are of some prognostic significance and, if abnormal at diagnosis, serve as a baseline to evaluate the effects of treatment. Liver function tests, although not particularly sensitive to the

presence of liver involvement, can influence treatment and treatment complications. A chest radiograph is particularly important for measuring the size of the mediastinal mass in relation to the maximal diameter of the thorax. Chest CT more clearly defines the extent of a mediastinal mass if present and identifies hilar nodes and pulmonary parenchymal involvement, which may not be evident on chest radiographs. Abdominal CT or MRI can identify gross subdiaphragmatic involvement of nodes together with enlargement and defects in the liver and spleen. Gallium-67 scan is particularly helpful in identifying areas of increased uptake, which can then be re-evaluated at the end of treatment, especially in patients with mediastinal masses that do not completely resolve on chest radiographs or CT. Lymphangiography, although unique in its ability to demonstrate intrinsic abnormalities in lymph nodes, is not without risk, is very labor intensive and uncomfortable, and fails to visualize upper para-aortic nodes. It is rarely performed in pediatric practice, where systemic therapy has become the cornerstone of treatment and would be expected to eliminate relatively small foci of disease.

Staging is based on involvement of lymph node regions (see Box 488–1 (Box Not Available)). Surgical staging is no longer routinely performed and

Box 488.1-2. Studies Necessary for Clinical Staging of Hodgkin Disease

Measurement of palpable lymph nodes, liver, and spleen

Bone marrow biopsy with advanced disease or ”B“ symptoms

Bone scan with elevated serum alkaline phosphatase level and/or bone pain

should be considered only if findings will significantly influence therapy. Bone marrow biopsy is necessary in only those patients with advanced (stage III or IV) disease or with “B” symptoms.

Treatment.

Because of concern about late effects, treatment of children in North America and Europe has evolved from primary treatment with extended-field radiation therapy to use of multiagent chemotherapy as the cornerstone of treatment, supplemented in selected cases by relatively low-dose involved-field irradiation (2,000–2,500 cGy). Treatment is largely determined by disease stage, patient's age at diagnosis, the presence or absence of “B” symptoms, and the presence of hilar lymphadenopathy and/or bulky nodal disease. Although there is not yet general agreement on their definitions, three risk groups have been identified. Favorable presentations include stages I and IIA. Intermediate presentations include stages I, IIB (with symptoms, bulky disease, or hilar lymphadenopathy), and stage IIIA. Unfavorable presentations include stages IIIB and IV.

FAVORABLE AND INTERMEDIATE PRESENTATIONS.

Cure rates with radiation alone (3,500–4,500 cGy) in surgically staged localized disease range from 40–80%, and the overwhelming majority of those who suffer relapse can be salvaged with a combination of multiagent chemotherapy or additional irradiation or both, resulting in cure rates of more than 90%. Unfortunately, this approach produces growth retardation in skeletally immature children and is associated with significant long-term morbidity, including thyroid failure, cardiac and pulmonary dysfunction, and an increased risk of breast cancer. For these reasons, many centers treating children and adolescents use combined modality therapy or even chemotherapy alone.

The chemotherapy regimens in current use are based on **MOPP** (nitrogen mustard [Mustargen], vincristine [Oncovin], procarbazine, and prednisone), or **ABVD** (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine), or variations and/or combinations of the two together with additional active agents such as etoposide and methotrexate. As originally conceived, a minimum of six cycles of chemotherapy was given with significant cumulative toxicity, including second malignancies, sterility, and cardiac and pulmonary dysfunction. The long-term toxicity is determined by the total dose of the agents. Newly developed “risk-adapted” programs are based on staging criteria as well as rapidity of response to initial chemotherapy. Their aim is to reduce total drug doses and treatment duration and even eliminate radiation therapy.

UNFAVORABLE PRESENTATIONS.

Chemotherapy, based on the same regimens used in early stage disease, is considered the primary treatment for patients with advanced disease, but the role of radiation is still under study. Because the cure rate with conventional drug combinations, with or without radiation therapy, is only 60–70%, newer and more aggressive regimens have been developed and are now in clinical trials.

RELAPSE.

Patients who suffer relapse after initial treatment with radiation alone or after an initial remission of more than 12 mo after chemotherapy alone or combined modality therapy usually respond to additional chemotherapy or radiation or both. Those who never achieve remission or who suffer relapse after an initial remission of less than 12 mo after chemotherapy or combined modality therapy have a poorer prognosis and are candidates for myeloablative chemotherapy and autologous stem cell or bone marrow rescue.

Prognosis.

Most treatment programs result in disease-free survival rates of more than 60%, with overall cure rates greater than 90% in those with early stage disease and more than 70% in more advanced cases. All newly diagnosed cases in children and adolescents should be treated with curative intent; this is consistently and effectively

achieved with combined modality therapy. The choice of regimen is then selected on the basis of risk category

---

and observed or anticipated long-term complications. Elimination of routine staging laparotomy and splenectomy avoids concerns about surgical morbidity and postsplenectomy infections.

488.2 Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma (NHL) results from malignant clonal proliferation of lymphocytes of T-, B-, or indeterminate cell origin. In the United States, NHL occurs with an annual incidence of 10.5 per million white and 7.3 per million black children younger than 20 yr of age. In equatorial Africa, 50% of childhood cancers are lymphomas, a result of the very high incidence of Burkitt lymphoma and possibly related to the immunosuppressive effects of malaria. Unlike that of Hodgkin disease, the incidence of NHL increases steadily throughout life. In some situations there is overlap with acute lymphoblastic or B-cell leukemia. Patients with lymphoblastic NHL and more than 25% lymphoblasts in the bone marrow are arbitrarily classified and treated as if they had acute lymphoblastic leukemia, whereas patients with B-cell ALL are treated similarly to patients with Burkitt lymphoma even if no extramedullary disease is present.

Pathogenesis.

EBV infection has a major role in the pathogenesis of Burkitt lymphoma. The EBV genome is present in tumor cells in 95% of “endemic” cases in equatorial Africa compared with 15% in “sporadic” cases in the United States. How EBV contributes to the pathogenesis of Burkitt lymphoma remains unclear. Congenital or acquired immunodeficiency also predisposes to the development of NHL. Epidemiologic studies have also implicated pesticide exposure as a possible risk factor.

Although elaborate classifications of NHL have been developed, they have little application to the pediatric disease. Most cases of NHL in children are high-grade, diffuse neoplasms. Three histologic subtypes are recognized: **lymphoblastic,** usually of T-cell origin; **small noncleaved cell lymphoma (SNCCL),** with Burkitt and non-Burkitt subtypes and of B-cell origin; and **large cell lymphoma (LCL),** with diffuse and anaplastic subtypes and of T-, B-, or indeterminate cell origin. The diagnosis and classification of childhood NHL requires considerable hematopathologic expertise and adequate diagnostic tissue, both fresh and frozen.

Different chromosomal translocations are specific for some histologic subtypes and involve various proto-oncogenes, resulting in malignant transformation through a variety of mechanisms. In SNCCL (Burkitt type), one of three chromosomal translocations [t(8;14), t(8;22), t(2;8)] results in approximation of the *MYC* proto-oncogene on chromosome 8 to a regulatory region of one of the immunoglobulin chain genes, resulting in dysregulation of *MYC*; in anaplastic LCL, fusion of the *NPM* gene on chromosome 5 with the *ALK* gene on chromosome 2 leads to formation of a chimeric protein that can influence cell growth and

proliferation.

Clinical Manifestations.

Presenting signs and symptoms vary with disease site and extent, and these in turn differ with histologic subtype.

Lymphoblastic NHL often presents as an intrathoracic tumor, usually a mediastinal mass, and is associated with dyspnea, chest pain, dysphagia, pleural effusion, and superior vena cava syndrome. Cervical or axillary lymphadenopathy is present in up to 80% of patients at diagnosis. Primary involvement of bone, bone marrow, testis, or skin is not uncommon. The central nervous system (CNS) may also be involved.

SNCCL presents as an abdominal tumor in 80% of U.S. cases in patients with abdominal pain or distention, bowel obstruction, change in bowel habits, intestinal bleeding, or, rarely, intestinal perforation. Other sites include CNS, bone marrow, and peripheral lymph nodes. Jaw involvement occurs in less than 20% of U.S. cases, compared with 70% of younger patients in equatorial Africa.

LCL occurs in many sites, including the abdomen and mediastinum. Extramedullary sites include skin, bone, and soft tissues. CNS involvement is rare, in contrast to SNCCL and lymphoblastic NHL.

Diagnosis.

Prompt tissue diagnosis and staging is important because of the rapid growth rate of lymphomas, especially SNCCL. To ensure adequate tissue for accurate diagnosis and subtyping, multiple needle biopsy specimens or a large wedge of tumor should be obtained. Several studies are necessary to accurately stage the disease and provide baseline measurements of organ function before treatment is instituted (Box 488–3). In cases with airway compromise, potential for anesthetic complications, and no easily accessible tissue to sample, empirical therapy may be started using corticosteroids.

The St. Jude staging system defines tumor extent, which is important for designing treatment (Box 488–4 (Box Not Available)). Stage I applies to localized disease, stage II to regional disease (except for mediastinal tumors, which are designated stage III), stage III to extensive disease, and stage IV to disseminated (CNS and/or bone marrow) disease. Elevated levels of serum lactic dehydrogenase (>500 U/L) correlate with tumor mass and have proved useful for stratifying therapy intensity.

LABORATORY FINDINGS.

Laboratory findings vary, depending on sites or organs involved. Elevated serum uric acid levels and other features of tumor lysis syndrome often complicate

---

the presentation of SNCCL. Elevated serum level of lactate dehydrogenase is a measure of tumor burden and may occur with any NHL subtype. A normal CBC does not preclude marrow involvement. CT or MRI of the chest or abdomen or both

provides key information on disease extent. Surgical staging is not necessary.

Treatment and Prognosis.

Surgical excision of localized intra-abdominal tumors often precedes the diagnosis of NHL and should always be attempted, if feasible. In this and other situations, multiagent chemotherapy is the primary treatment. Tumor lysis syndrome (i.e., high serum potassium, uric acid, and high phosphorus with low calcium levels) frequently complicates initial treatment of disseminated disease. Appropriate hydration with addition of sodium bicarbonate to produce dilute alkaline urine, administration of allopurinol, and correction of electrolyte abnormalities are essential to minimize this life-threatening complication.

In contrast to HD, second malignancies and infertility have not been major problems in long-term survivors of NHL.

EARLY-STAGE NHL.

Unlike HD, NHL is considered a disseminated disease from the time of diagnosis. Even patients with apparently localized and resected disease require chemotherapy. Patients with stage I/II NHL, irrespective of histologic subgroup, are effectively treated with six cycles of **COMP** (cyclophosphamide, vincristine [Oncovin], methotrexate, and prednisone) or three cycles of **COPA** (substituting doxorubicin for methotrexate) followed by 6 mo of mercaptopurine and methotrexate or, in the case of T-cell lymphoblastic NHL, an acute lymphoblastic leukemia–like regimen. About 90% of cases are cured with these regimens. The emphasis now is on decreasing morbidity of therapy for these children while maintaining the high cure rate.

ADVANCED-STAGE NHL.

Patients with stage III/IV NHL are best treated with therapy based on the histologic subtype.

Lymphoblastic lymphoma is treated with intensive chemotherapy regimens, generally of 2 yr duration and consisting of multiple chemotherapeutic agents given in cycles or a regimen based on those used for high-risk acute lymphoblastic leukemia. Cranial radiation, intrathecal chemotherapy, and/or high-dose methotrexate are important for prevention of CNS disease. Early relapses require cytoablative chemotherapy, followed by allogeneic bone marrow transplantation, if possible.

SNCCL is treated with relatively short-duration (3–6 mo) intensive chemotherapy regimens, including an alkylating agent (usually cyclophosphamide) coupled with other active systemic agents (vincristine, prednisone, methotrexate, cytarabine, etoposide, and/or doxorubicin) and intrathecal therapy, which produces survival rates of more than 90% in localized and 70–80% in those with disseminated disease. If relapse occurs, it becomes evident in the 1st yr after diagnosis and is often rapidly progressive and relatively resistant to additional therapy, especially in patients with stage IV disease.

LCL is treated with intensive multiagent chemotherapy regimens similar to those used for lymphoblastic lymphoma, which have produced long-term survival rates of 50–70% in those of T-cell origin. For B cell–derived LCL, short, intensive regimens as outlined earlier for SNCLL have produced 6-yr event-free survival as high as 95%.

Chapter 489 - Brain Tumors in Childhood

John F. Kuttesch Jr.
Joann L. Ater

Primary central nervous system (CNS) tumors are a heterogeneous group of diseases that collectively are the second most frequent malignancy in childhood and adolescence. Mortality among this group approaches 45%. In addition, these patients have the highest morbidity, primarily neurologic, of all childhood malignancies. However, outcomes have improved over time, owing to innovations in neurosurgery and radiation therapy as well as to identification of chemotherapy as a therapeutic modality. The treatment approach for these tumors is multimodal. Surgery with complete resection, if feasible, is the foundation of this approach. Based on the diagnosis, patient age, and other factors, radiation therapy and/or chemotherapy are used.

Epidemiology.

Approximately 2,200 primary brain tumors are diagnosed each year in children and adolescents, with an overall annual incidence of 28 cases/per million children. There is a higher incidence of CNS tumors in infants and young children up to 7 yr of age (~36 cases/million children annually) compared with older children and adolescents (~21 cases/million children annually) (Fig. 489–1).

Pathogenesis.

Among the more than 100 histologic categories and subtypes of primary brain tumors described in the World Health Organization (WHO) classification of tumors of the CNS and meninges, 5 categories (juvenile pilocytic astrocytoma, medulloblastoma/primitive neuroectodermal tumor [PNET], diffuse astrocytomas, ependymoma, and craniopharyngioma) constitute 80% of all pediatric brain tumors (Table 489–1).

In a survey of children with sampled brain tumors, the Childhood Brain Tumor Consortium reported a slight predominance of infratentorial tumor location (43.2%), followed by the supratentorial location (40.9%), spinal cord (4.9%), and multiple sites (11%). There are age-related differences in primary location of tumor (Fig. 489–2). Within the 1st year of life, supratentorial tumors predominate and include, most commonly, choroid plexus complex tumors and teratomas. From 1–10 yr of age, infratentorial tumors predominate, owing to the high incidence of juvenile pilocytic astrocytoma and medulloblastoma. After 10 yr of age, once again, supratentorial tumors predominate, with the diffuse astrocytomas most common. Tumors of the optic pathway and hypothalamus region, the brainstem, and pineal-midbrain region occur with a greater incidence in children and adolescents than in adults.

There is little understanding of the etiology of pediatric brain tumors. A male predominance is noted in the incidence of medulloblastoma and ependymoma. Familial and hereditary syndromes associated with increased incidence of brain tumors account for approximately 5% of cases (Table 489–2). Cranial exposure to ionizing radiation is also associated with an increased incidence of brain tumors. Additionally, there are sporadic reports of brain tumors within families without evidence of a heritable syndrome. The molecular events associated with

Figure 489-1 Age-specific incidence rates of malignant brain tumors of childhood from SEER 1986–1994. (From Gurney JC, Smith MA, Bunin GR: *National Cancer Institute SEER Program*. NIH publication No. 99-4649, 1999, pp 51–63.)

tumorigenesis of pediatric brain tumors are not known; however, our understanding of the molecular biology of these diseases is expanding.

Clinical Manifestations.

The clinical presentation of patients with brain tumors depends on the tumor location, tumor type, and the age of the child. Signs and symptoms are related to the tumor causing obstruction of cerebrospinal fluid (CSF) drainage paths, leading to increased intracranial pressure (ICP) and/or

TABLE 489-1 -- **Distribution of Childhood Brain Tumors Based on Histology**

Histology	Distribution (% of total)
Medulloblastoma/PNET	20
Juvenile pilocytic astrocytoma	20
Low-grade astrocytoma	15
High-grade astrocytoma	7
Ependymoma	7
Craniopharyngioma	7
Unclassified primary tumors	7

causing focal brain dysfunction. Subtle changes in personality, mentation, and/or speech may precede these classic signs and symptoms of brain tumors. In young children the diagnosis of a brain tumor may be delayed because their symptoms are similar to those of more common illnesses, such as gastrointestinal disorders. Infants with open cranial sutures may present with the common signs of increased ICP (vomiting, lethargy, and irritability) as well as macrocephaly. The classic triad of headache, nausea and/or vomiting, and papilledema is associated with midline or infratentorial tumors. Disorders of equilibrium, gait, and coordination occur with infratentorial tumors. Torticollis may result in patients with cerebellar tonsil herniation. Blurred vision, diplopia, and nystagmus are also associated with infratentorial tumors. Brainstem region tumors may be associated with gaze palsy, cranial nerve palsies, and upper motor neuron deficits (hemiparesis, hyperreflexia, and clonus). Supratentorial tumors are more commonly associated with focal disorders such as motor weaknesses, sensory changes, speech disorders, seizures, and reflex abnormalities. Infants with supratentorial tumors may present with hand preference. Optic pathway tumors present with visual disturbances such as decreased visual acuity, Marcus Gunn pupil (afferent papillary defect), nystagmus, and/or visual field defects. Suprasellar region tumors and third ventricular region tumors may present initially with neuroendocrine deficits such as diabetes insipidus and hypothyroidism. **The diencephalic syndrome,** a classic presentation of failure to

Figure 489-2 Childhood brain tumors occur at any location within the central nervous system. The relative frequency of brain tumor histologic types and the anatomic distribution are shown. (From Albright AL: Pediatric brain tumors. *CA Cancer J Clin* 1993;43:272–88.)

thrive, emaciation, increased appetite, and euphoric affect, occurs in infants with tumors in these regions. **Parinaud syndrome,** a classic presentation of pineal region tumors, is manifested by (1) paresis of upward gaze, (2) pupillary dilatation reactive to accommodation but not to light, (3) nystagmus to convergence or retraction, and (4) eyelid retraction. Spinal cord tumors and spinal cord dissemination of brain tumors may manifest as long nerve tract motor and/or sensory deficits, bowel and bladder deficits, and back or radicular pain. Patients with meningeal metastatic disease from brain tumors or leukemia may present with signs and symptoms similar to those of patients with infratentorial tumors.

Diagnosis.

The evaluation of a patient suspected to have a brain tumor is an emergency. Initial evaluation should include a complete history, physical examination, and neurologic assessment with neuroimaging. For primary brain tumors, MRI is the neuroimaging standard. Tumors in the pituitary/suprasellar region, optic path, and infratentorium are better delineated with MRI than with CT. Patients with tumors of the midline and the pituitary/suprasellar/optic chiasmal region should undergo evaluation for neuroendocrine dysfunction. Formal ophthalmologic examination is beneficial in patients with optic path region tumors to document impact of the disease on oculomotor function, visual acuity, and fields of vision. The suprasellar region and pineal region are preferential sites for germ cell tumors. Both serum and CSF

measurements of ß-human chorionic gonadotropin and a-fetoprotein can assist in the diagnosis of germ cell tumors. In tumors with the propensity of spreading to the leptomeninges such as medulloblastoma/PNET, ependymoma, and germ cell tumors, lumbar puncture and cytologic analysis of the CSF is indicated; however, lumbar puncture is contraindicated in individuals with newly diagnosed hydrocephalus secondary to CSF flow obstruction or in individuals with infratentorial tumors. Lumbar puncture in these individuals may lead to brain herniation, resulting in neurologic compromise and death.

ASTROCYTOMAS.

Astrocytomas are the most common pediatric brain tumors and comprise a heterogeneous group of tumors accounting for approximately 40% of cases. These tumors occur throughout the CNS.

Low-grade astrocytomas (LGAs) are the predominant group of astrocytomas in childhood and are characterized by their indolent clinical course. The two most common types of LGAs are the pilocytic astrocytomas and the fibrillary infiltrating astrocytomas. **Juvenile pilocytic astrocytoma (JPA)** is the most common astrocytoma in children, comprising 20% of all brain tumors. Based on clinicopathologic features using the WHO Classification System, JPA is classified as a WHO grade I tumor. Although JPA can occur anywhere in the CNS, the classic site of presentation is the cerebellum. Other common sites include the hypothalamic/third ventricular region and the optic nerve and chiasmal region. The classic but not exclusive neuroradiologic findings of JPA are the presence of a contrast medium–enhancing nodule within the wall of a cystic mass (Fig. 489–3). The microscopy findings exhibit a biphasic appearance of bundles of compact fibrillary tissue interspersed with loose microcystic, spongy areas. The presence of **Rosenthal fibers,** condensed masses of glial filaments occurring in the compact areas, helps to establish the diagnosis. JPA has a low metastatic potential and is rarely invasive. A small proportion of these tumors can progress and develop leptomeningeal spread, particularly tumors occurring in the optic path region. JPA very rarely undergoes malignant transformation to a more aggressive tumor. JPA of the optic nerve and chiasmal region is a relatively common finding in patients with neurofibromatosis type 1 (15% incidence). Unlike diffuse fibrillary astrocytomas, there are no characteristic cytogenetic abnormalities in JPA nor are there any known molecular abnormalities. Other tumors occurring in the pediatric age group with similar clinicopathologic characteristics as JPA include pleomorphic xanthoastrocytoma, desmoplastic cerebral astrocytoma of infancy, and subependymal giant cell astrocytoma. The fibrillary astrocytomas are a group of tumors characterized by a pattern of diffuse infiltration of tumor cells among normal neural tissue and a potential for anaplastic progression. Based on their clinicopathologic characteristics, they are grouped as low-grade astrocytomas (WHO grade II), malignant astrocytomas (anaplastic astrocytoma [AA, WHO grade III), and glioblastoma multiforme (GBM, WHO grade IV). Of this group the fibrillary LGA is the second most common astrocytoma in children, accounting for 15% of brain tumors. Histologically, these low-grade tumors demonstrate increased cellularity compared with normal brain parenchyma, with few mitotic figures, nuclear pleomorphism, and microcysts. The characteristic MRI finding is the lack of enhancement after contrast agent infusion. Molecular genetic abnormalities found among low-grade diffuse infiltrating astrocytomas include mutations of *TP53* and overexpression of platelet-derived growth factor a-chain and platelet-derived growth factor receptor-a. These tumors have the potential to evolve into malignant astrocytomas, a development that is associated with cumulative acquisition of multiple molecular abnormalities.

The clinical management of LGAs focuses on a multimodal approach incorporating surgery, radiation therapy, and/or chemotherapy. Outcome among patients with JPA is better than outcome among those with fibrillary LGAs. Surgery is the primary therapeutic modality for LGAs. After complete surgical

Figure 489-3 T1 weighted sequence post gadolinium MR (axial image) in a 4-yr-old boy presenting with headaches, nausea and vomiting, and ataxia who was found to have a juvenile pilocytic astrocytoma. (Adapted from Fuller GN: Central nervous system tumors. In Parham DM [editor]: *Pediatric Neoplasia: Morphology and Biology*. Philadelphia, Lippincott–Raven, 1996, pp 153–204.)

resection the overall survival approaches 80–100%. In patients with partial resection (<90% resection), overall survival varies from 50–95% depending on the anatomic location of the tumor. In those patients with partial resection and stable neurologic status, the current approach is to follow the patient closely by examination and imaging. With evidence of progression, surgical re-resection should be considered. In those patients in whom second surgery was less than complete or not feasible, radiation therapy is of benefit. Radiation therapy is given to the tumor bed at a total cumulative dose ranging from 50–55?Gy given at a daily schedule over 6 wk. Historically, patients with deep midline tumors were treated empirically without surgery or biopsy using radiation therapy, with variable survival rates from 33–75%. However, modern surgical techniques and innovative radiation therapy methodology may positively impact on the survival and clinical outcome of these patients. The role of chemotherapy in management of LGAs is evolving. Because of the concerns for young children of the morbidity from radiation therapy, several chemotherapy approaches have been evaluated, especially in children younger than 5 yr of age. Complete response to chemotherapy is low; however, these approaches have yielded prolonged disease control in 70–100% of patients. Patients with midline tumors as in the hypothalamic/optic chiasmatic region have tended to do less well. Taken together, the chemotherapy approaches have permitted delay and, potentially, avoidance of radiation therapy. Currently, in a national trial investigators are comparing the effectiveness and tolerance between a carboplatin-based chemotherapy schedule and a lomustine (CCNU)-based schedule in children younger than 10 yr of age with a progressive LGA. Observation is the primary approach in clinical management of selective patients with LGAs that are biologically indolent. One group includes patients with neurofibromatosis 1 who may develop an LGA of the optic chiasm/optic pathway or brainstem that is found incidentally. Another group is patients with midbrain astrocytomas who have resolution of clinical symptoms after ventricular shunting and do not require further intervention.

Malignant astrocytomas are much less common in children and adolescents than in adults, accounting for 7–10% of all childhood tumors. Among this group, **anaplastic astrocytoma** (WHO grade III) is more common than **glioblastoma multiforme** (WHO grade IV). The histopathology of anaplastic astrocytomas demonstrates increased cellularity compared with low-grade diffuse astrocytomas, cellular and

nuclear atypia, presence of mitoses, and, variably, microvascular proliferation. Characteristic histopathology findings in glioblastoma multiforme include dense cellularity, high mitotic index, microvascular proliferation, and foci of tumor necrosis. There is limited information regarding the molecular abnormalities in malignant astrocytomas of children. Overexpression of P53 in malignant astrocytomas of children is an adverse prognostic factor. The frequency of mutations in *TP53* in childhood malignant astrocytomas is similar to that noted in adults; however, the frequency of such mutations in malignant astrocytomas of children younger than 3 yr of age is lower. These observations suggest differing mechanisms of oncogenesis between young children (<3 yr old) and older children. As in adults, optimal therapeutic approaches for malignant astrocytomas have yet to be defined. The "standard therapy" continues to be surgical resection followed by involved-field radiation therapy, although patient outcome is poor.

Oligodendrogliomas are uncommon tumors of childhood. These infiltrating tumors occur predominately in the cerebral cortex and originate in the white matter. In childhood, oligodendroglioma, a well-differentiated neoplasm, predominates. Histologically, oligodendrogliomas are composed of rounded cells with little cytoplasm and the presence of microcalcifications. Observation of a calcified cortical mass on CT in a patient presenting with a seizure is suggestive of oligodendroglioma. Treatment approaches are similar to those for infiltrating astrocytomas.

MIXED GLIOMAS.

Mixed gliomas are composed of two or more distinct glial cell types (astrocytoma, oligodendroglioma, and/or ependymoma) and occur uncommonly in pediatric patients.

EPENDYMAL TUMORS.

Ependymal tumors are derived from the ependymal lining of the ventricular system. Ependymoma (WHO grade II) is the most common of these neoplasms, occurring predominately in childhood and accounting for 10% of childhood tumors. Approximately 70% of ependymomas in childhood occur in the posterior fossa. The mean age of patients is 6 yr, with approximately 30% of cases occurring in children younger than 3 yr of age. The incidence of leptomeningeal spread approaches 10% overall. Clinical presentation is dependent on the anatomic location of the tumor. MRI demonstrates a well-circumscribed tumor with variable and

complex patterns of gadolinium enhancement with or without cystic structures. These tumors generally are noninvasive, extending into the ventricular lumen and/or displacing normal structures. Histologic characteristics of these tumors include perivascular pseudorosettes, ependymal rosettes, monomorphic nuclear morphology, and occasional nonpalisading foci of necrosis. Surgery is the primary treatment modality, with extent of surgical resection a major prognostic factor. Two other major prognostic factors are age, with younger children having poorer outcomes, and tumor location, with localization in the posterior fossa that is often seen in young children associated with poorer outcomes. Surgery alone is rarely curative. Multimodal therapy incorporating radiation with surgery has resulted in long-term survival in approximately 40% of patients after gross total resection. Recurrence is predominately local. Ependymoma is sensitive to a spectrum of chemotherapeutic agents; however, the role of chemotherapy in multimodal therapy of ependymoma is still unclear. Several limited trials have shown no benefit to the use of high-dose chemotherapy with peripheral blood stem cell rescue in ependymoma. Current investigations are directed toward identification of optimal radiation dose, surgical questions addressing the use of second-look procedures after chemotherapy, and further evaluation of classic as well as novel chemotherapeutic agents. There are no characteristic cytogenetic or molecular genetic alterations in ependymoma. However, preliminary studies suggest that there are genetically distinct subtypes, exemplified by an association between alterations in the *NF2* gene and spinal ependymoma. **Anaplastic ependymoma** (WHO grade III) is much less common in childhood, and these tumors are characterized by a high mitotic index and histologic features of microvascular proliferation and pseudopalisading necrosis. **Myxopapillary ependymoma** (WHO grade I) is a slow-growing tumor arising from the filum terminale and conus medullaris.

CHOROID PLEXUS TUMORS.

Choroid plexus tumors account for 2–4% of childhood CNS tumors. They are the most frequent CNS tumor in children younger than 1 yr of age and account for 10–20% of CNS tumors occurring in infancy. These tumors are intraventricular papillary neoplasms arising from choroid plexus epithelium. Children present with signs and symptoms of increased ICP. Infants may present with macrocephaly and focal neurologic deficits. In children, these tumors occur predominately supratentorially in the lateral ventricles. **Choroid plexus papilloma** (WHO grade I), the most common of this group, is a well-circumscribed lesion by neuroimaging and closely resembles normal choroid plexus histologically. **Choroid plexus carcinoma** (WHO grade III) is a malignant tumor with metastatic potential to seed into the CSF pathways. This malignancy has histologic characteristics of nuclear pleomorphism, high mitotic index, and increased cell density. Immunopositivity for transthyretin (prealbumin) is useful in confirming the diagnosis of these tumors. These tumors are associated with the Li-Fraumeni syndrome. Simian virus 40 (SV40) may play an etiologic role in choroid plexus tumors. After complete surgical resection, outcome for choroid plexus papilloma approaches 100% whereas outcome for choroid plexus carcinoma approaches 20–40%. Reports suggest that radiation therapy and/or chemotherapy may lead to better disease control for choroid plexus carcinoma.

EMBRYONAL TUMORS.

Embryonal tumors or **primitive neuroectodermal tumors (PNET)** are the most common group of malignant CNS tumors of childhood, accounting for 20–25% of pediatric CNS tumors. These tumors have the potential to metastasize to the neuraxis. This group includes medulloblastoma, supratentorial PNET, ependymoblastoma, medulloepithelioblastoma, and atypical teratoid/rhabdoid tumor (ATRT). These tumors are histologically classified as WHO grade IV tumors.

Medulloblastoma, accounting for 90% of embryonal tumors, is a cerebellar tumor occurring predominately in males and at a median age of 5–7 yr. The majority of

tumors occur in the midline cerebellar vermis; however, older patients may present with tumors in the cerebellar hemisphere. CT demonstrates a solid, homogeneous, contrast medium–enhancing mass in the posterior fossa causing 4th ventricular obstruction and hydrocephalus. MRI shows similar characteristics. Up to 30% of patients present with neuroimaging evidence of leptomeningeal spread. Among a variety of diverse histologic patterns of this tumor, the most common is a monomorphic sheet of undifferentiated cells classically noted as small, blue, round cells. Neuronal differentiation is more common among these tumors and histologically characterized by the presence of Homer Wright rosettes and by immunopositivity for synaptophysin. Patients present with signs and symptoms of increased intracranial pressure (headache, nausea, vomiting, mental status changes, and hypertension) and cerebellar dysfunction (ataxia, poor balance, dysmetria). Standard clinical staging evaluation includes MRI of brain and spine, both preoperatively and postoperatively, as well as lumbar punctures. The Chang staging system, originally based on surgical information, has been modified to incorporate information from neuroimaging to identify risk categories. Clinical features that have consistently demonstrated prognostic significance include age at diagnosis, extent of disease, and extent of surgical resection. Younger patients (<4 yr of age) have poor outcome that is partly caused by a higher incidence of disseminated disease on presentation and past therapeutic approaches that have used less intense therapies. Patients with disseminated disease at diagnosis (M > 0), including positive CSF cytology alone (M1), have a markedly worse outcome than those patients with no dissemination (M0). Similarly, patients with gross residual disease after surgery have worse outcomes compared with those who had gross total resection of their disease.

Multimodal treatment approach is pursued in medulloblastoma, with surgery being the cornerstone of treatment. Medulloblastoma is both a chemotherapy-sensitive and irradiation-sensitive disease. Historically, surgery alone was ineffective. In the 1940s radiation therapy was found to be effective, improving overall outcome to a 30% survival rate. With technologic advances in neurosurgery, neuroradiology, and radiation therapy, as well as identification of chemotherapy as an effective modality, overall outcome among all patients approaches 60–70%. Standard radiation treatment in medulloblastoma incorporates craniospinal radiation at a total cumulative dose of 30–36?Gy with a cumulative dose of 50–55?Gy to the tumor bed. Craniospinal radiation at this dose in very young children (those < 4 years) results in severe late neurologic sequelae, including microcephaly, learning disabilities, mental retardation, neuroendocrine dysfunction (growth failure, hypothyroidism, hypogonadism, and absent/delayed puberty), and/or second malignancies. Similarly, in older children, late sequelae, such as learning disabilities, neuroendocrine dysfunction, and/or second malignancies, can occur. These observations have resulted in stratification of treatment approaches into three strata: (1) patients younger than 4 yr of age; (2) standard risk patients age 4 yr and older with surgical total resection and no disease dissemination (M0); and (3) high-risk patients age 4 yr and older with disease dissemination (M > 0) and/or bulky residual disease after surgery.

Cytogenetic and molecular genetic studies have demonstrated multiple abnormalities in medulloblastoma. The most common cytogenetic abnormality involves chromosome 17p deletions. Molecular studies have identified these lesions as the most common molecular defect in medulloblastoma, occurring in 30–40% of all cases. These deletions are not associated with *TP53* mutations. In 10–20% of medulloblastoma cases, genetic material losses are noted on chromosomes 1q and 10p. In approximately 10% of cases, abnormalities of 9p have been detected.

Molecular lesions in this region are associated with

---

inactivation of the human homologue of the hedgehog/patched signaling pathway and are implicated in the nevoid basal cell carcinoma syndrome. The finding of mutations in the *APC* gene and ß-catenin gene suggests the involvement of the Wnt pathway in the pathogenesis of medulloblastoma. Increased *PAX5* and *PAX6* gene expression in medulloblastoma suggests that abnormalities in neural transcription factors may play a role in early tumorigenesis of these tumors. Most recently, high expression of neurotrophin receptor TrkC and low expression of the oncogene *MYC* have been demonstrated to be associated with favorable outcome and appear to be strong independent prognostic factors. Further analysis has shown that the cohort of patients with tumors with high expression of TrkC and low expression of *MYC* have very favorable outcomes independent of clinical prognostic factors. With the evolution of gene array technology, recent preliminary studies have identified clusters of genes/gene expression that appear to be associated with metastatic medulloblastoma and outcome. Using gene micro array technology and the development of proteomic technology will, it is hoped, offer insight into the molecular events associated with medulloblastoma tumorigenesis. Additionally, information obtained may lead to novel molecularly targeted approaches in this disease.

Supratentorial primitive neuroectodermal tumors (SPENT) account for 2–3% of childhood brain tumors primarily in children within the 1st decade of life. These tumors are similar histologically to medulloblastoma and composed of undifferentiated or poorly differentiated neuroepithelial cells. Historically, patients with SPNET have had poorer outcomes than those with medulloblastoma after combined modality therapy. In current clinical trials, children with these tumors are considered among the high-risk group and received dose-intense therapy with craniospinal radiation therapy.

Atypical teratoid/rhabdoid tumor (ATRT) is a very aggressive embryonal malignancy that occurs predominantly in children younger than 5 yr of age and can occur at any location in the neuraxis. The histology demonstrates a heterogeneous pattern of cells, including rhabdoid cells that express epithelial membrane antigen and neurofilament antigen. The characteristic cytogenetic pattern is partial or complete deletion of chromosome 22q that has been associated with mutation in the *INI1* gene. The relationship between this mutation and tumorigenesis is unclear. Outcome after combined modality therapy with intensive chemotherapy is very poor.

Ependymoblastoma and **medullomyoblastoma** are rare, highly malignant embryonal tumors of early childhood and infancy.

PINEAL PARENCHYMAL TUMORS.

The pineal parenchymal tumors are the second most common malignancies after germ cell tumors that occur in the pineal region. These include pineoblastoma, occurring predominantly in childhood, pineocytoma, and the mixed pineal parenchymal tumors. Therapeutic approach in this group of diseases is multimodal. In the past there was significant concern owing to the location of these masses and

the potential complications of surgical intervention. With recent developments in neurosurgical technique and surgical technology, the morbidity and mortality associated with these approaches have markedly decreased. Stereotactic biopsy of these tumors may be adequate to establish diagnosis; however, consideration should be pursued for total resection of the lesion before institution of additional therapy. Pineoblastoma is the more malignant variant and is considered a subgroup of PNETs of childhood. Chemotherapy regimens incorporate cisplatin, cyclophosphamide (Cytoxan), etoposide (VP-16), and vincristine and/or lomustine. Data have shown that survival outcome of pineal region PNETs with combined modality therapy of chemotherapy and radiation approaches 70% at 5 yr, similar to that noted for medulloblastoma. Pineocytoma is a disease that is generally approached with surgical resection.

NEURONAL/MIXED NEURONAL-GLIAL TUMORS.

These tumors are a heterogeneous group of tumors that are slow growing and of low malignant progression. They are associated with favorable outcome after surgical resection. They are categorized as WHO grade I or WHO grade II tumors. The diseases within this category include ganglioglioma, dysembryoplastic neuroepithelial tumor, desmoplastic infantile astrocytoma, and desmoplastic infantile ganglioglioma.

CRANIOPHARYNGIOMA.

Craniopharyngioma (WHO grade I) is a common tumor of childhood, accounting for 7–10% of all childhood tumors. The adamantinomatous variant of craniopharyngioma predominates in childhood. These tumors are solid with cystic components and occur within the suprasellar region. These tumors are minimally invasive, adhere to adjacent brain parenchyma, and engulf normal brain structures. MRI demonstrates the solid tumor with cystic structures containing fluid of intermediate density. CT may show calcifications associated with the solid and cystic wall components. Surgery is the primary treatment modality, with gross total resection curative in small lesions. Controversy exists in the relative roles of surgery and radiation therapy in large, complex tumors. There is significant morbidity (panhypopituitarism, growth failure, visual loss) associated with these tumors and their therapy owing to the anatomic location. No role has been identified for chemotherapy in craniopharyngioma.

MENINGEAL TUMORS.

Meningiomas are uncommon tumors of childhood. These tumors arise from the arachnoid layer of the meninges and are generally very slow growing. Among children, a large proportion of these tumors can be associated with either a genetic disposition such as neurofibromatosis 2 or basal cell nevus syndrome or prior radiation exposure (secondary malignancy).

GERM CELL TUMORS.

Germ cell tumors of the CNS are a heterogeneous group of tumors that are primarily tumors of childhood arising predominantly in midline structures of the pineal and suprasellar regions. They account for 1–2% of pediatric brain tumors. The peak incidence of these tumors is 10–12 yr of age. Overall, there is a male preponderance, although there is a female preponderance for suprasellar tumors. These tumors can occur multifocally in 5–10% of cases. This group of tumors is much more prevalent in Asian populations than European populations. As in peripheral germ cell tumors, the analysis of protein markers, a-fetoprotein, and ß-human chorionic gonadotropin may be useful in establishing the diagnosis and monitoring treatment response. Surgical biopsy is recommended to establish the diagnosis; however, nongerminomatous germ cell tumors may be diagnosed based on protein marker elevations. Therapeutic approaches to germinomas and mixed germ cell tumors are different. The survival proportion among patients with pure germinoma exceeds 90%. The postsurgical treatment of pure germinomas is somewhat controversial in defining the relative roles of chemotherapy and radiation therapy. Excellent outcomes are reported in patients who have received local field doses of radiation of more than 40?Gy and craniospinal radiotherapy. Similarly, groups have reported excellent outcomes when chemotherapy has been incorporated in regimens that utilize reduced doses of radiation therapy (24?Gy to the local field alone). More recently, clinical trials have investigated the use of chemotherapy alone after surgery in pure germinomas. The therapeutic approach in nongerminomatous germ cell tumors is more aggressive, combining more intense chemotherapy regimens with craniospinal radiation therapy. Survival rates among these tumors are markedly less than noted in germinoma, ranging from 40–70% at 5 yr. Recent trials have shown benefit using high doses of chemotherapy with blood stem cell rescue. If confirmed in larger studies, future approaches may test the use of high doses of chemotherapy with dose-reduced radiation therapy.

TUMORS OF THE BRAINSTEM.

Tumors of the brainstem comprise 10–15% of childhood primary CNS tumors. This is a heterogeneous group of tumors. Outcome is associated with tumor location, imaging characteristics, and clinical status of the patient. Patients with these tumors may present with motor weakness, cranial nerve deficits, cerebellar deficits, and/or signs of increased intracranial pressure. Based on MR evaluation and clinical findings, tumors of the brainstem can be classified into four types: (1) focal, 5–10% of patients; (2) dorsally exophytic, 5–10% of patients; (3) cervicomedullary, 5–10% of patients; and (4) diffuse intrinsic tumors, 70–85% of patients. Surgical resection is the primary treatment approach for focal and dorsally exophytic tumors leading to a favorable outcome. Histologically, these two groups are generally low-grade gliomas. Cervicomedullary tumors, owing to their location, may not be amenable to surgical resection but are radiotherapy sensitive. Diffuse intrinsic tumors, characterized by the diffuse infiltrating pontine glioma, are associated with very poor outcome independent of histologic diagnosis (Fig. 489–4). These tumors are not amenable to surgical resection. Biopsy in children with MR findings of a diffuse intrinsic tumor is controversial and is not recommended unless there is suspicion of another diagnosis, such as infection, demyelination, vascular malformation, multiple sclerosis, or metastatic tumors. These diagnoses are much more common in adults. The standard approach for treatment in diffuse infiltrating pontine gliomas has been radiation therapy; however, median survival associated with this treatment is 12 mo, at best. Use of chemotherapy, including high-dose chemotherapy with blood stem cell rescue, has not been of survival benefit in this group of patients. Current approaches include evaluation of investigational agents alone or in combination with

radiation therapy, similar to approaches being pursued in patients with malignant gliomas.

METASTATIC TUMORS.

Metastatic spread of other childhood malignancies to the brain is uncommon. Childhood acute lymphoblastic leukemia and non-Hodgkin lymphoma can

Figure 489-4 T1 weighted sequence post-gadolinium MRI (sagittal image) of a pontine diffuse infiltrating glioma in a 10-yr-old girl presenting with headache, cranial nerve palsies, and left-sided weakness. (Modified from Kleihues P, Cavenee WK: *World Health Organization Classification of Tumors: Pathology and Genetics of Tumors of the Nervous System*. Lyon, IARC Press, 2000.)

spread to the leptomeninges, causing symptoms of communicating hydrocephalus. Chloromas, which are collections of myeloid leukemia cells, can occur throughout the neuraxis. Rarely, brain parenchymal metastases occur from lymphoma, neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, osteosarcoma, and clear cell sarcoma of the kidney. Therapeutic approaches are based on the specific histologic diagnosis and may incorporate radiation therapy, intrathecal administration of chemotherapy, and/or systemic administration of chemotherapy. Medulloblastoma is the most common childhood brain tumor to metastasize extraneuronally. Less commonly, extraneuronal metastases from malignant glioma, PNET, and ependymoma can occur. Ventriculoperitoneal shunts have been known to allow extraneural metastases, primarily within peritoneal cavity but also systemically.

Complications and Long-Term Management.

Data from the National Cancer Institute SEER Program indicate that more than 70% of patients with childhood brain tumors will be long-term survivors. At least one half of these survivors will experience chronic problems as a direct result of their tumor and treatment. These include chronic neurologic deficits such as focal motor and sensory abnormalities, seizure disorders, neurocognitive deficits (developmental delays, learning disabilities), and neuroendocrine deficiencies (hypothyroidism, growth failure, delayed or absent puberty). Additionally, these patients are at significant risk of secondary malignancies. The impact of these chronic complications in these survivors of childhood brain tumors on their quality of life is only now being to be appreciated.

Future Directions.

Efforts will continue to define more specific and selective chemotherapeutic agents and to refine the use of radiation therapy. Technologic advances have made feasible extensive laboratory studies of genomics and, soon, proteomics in childhood malignancies. A major effort is being directed to understand the molecular biology of tumorigenesis, cellular proliferation and survival, and metastasis in childhood brain tumors. The underlying mechanisms of these processes may be different among primary childhood malignancies compared with malignancies of adulthood. National and international collaborative research efforts are ongoing to elucidate the molecular events associated with these processes. The ultimate goal is translation of this information to define molecular targets for the development of novel therapeutic approaches in these diseases.

Chapter 490 - Neuroblastoma

Joann L. Ater

Epidemiology.

Neuroblastoma (NB) is an embryonal cancer of the peripheral sympathetic nervous system. It is the third most common pediatric cancer, accounting for about 8% of childhood malignancies. About 500 new cases are diagnosed each year in the United States. NB is the most frequently diagnosed neoplasm in infants, accounting for 28–39% of neonatal malignancies. The median age at diagnosis is 2 yr; 90% of cases are diagnosed before 5 yr of age. The incidence is slightly higher in males and in whites.

Pathogenesis.

NB includes a spectrum of tumors with variable degrees of neural differentiation, ranging from undifferentiated small round cells (neuroblastoma) to tumors containing mature ganglion cells (ganglioneuroblastoma or ganglioneuroma). The tumors may resemble other small round cell tumors, such as rhabdomyosarcoma, Ewing sarcoma, and non-Hodgkin lymphoma.

The prognosis varies with the histologic definition of tissue pattern (Shimada classification). A favorable prognosis NB subtype is based on the amount of stroma, degree of tumor cell differentiation, and number of tumor cell mitoses.

The genetic event that initially triggers formation of NB is not known. The pathogenesis is likely to be related to a succession of mutational events, prenatally and perinatally, that may be caused by environmental and genetic factors. Increased incidence of NB is associated with some maternal and paternal occupational chemical exposures, work in farming, and work related to electronics. Familial NB is found in 1–2% of cases. Genetic characteristics of NB that are of prognostic importance and currently used along with clinical factors to determine treatment include amplification of the *MYCN* (N-*myc*) proto-oncogene and hyperdiploidy of tumor cell DNA content (Table 490–1). Amplification of *MYCN* has prognostic importance independent of stage and age and is strongly associated with advanced tumor stage and poor outcome. Hyperdiploidy confers better prognosis if the child is younger than 1 yr of age at diagnosis. Genetic abnormalities, including loss of heterozygosity (LOH) of 1p, 11q, and 14q, and gain of 17q, are found commonly in

NB tumor tissue. In addition, other biologic factors that correlate with prognosis include the level of nerve growth factor receptor (Trk-A) expression, multidrug-resistance–associated protein, and telomerase activity. These factors are under investigation in clinical trials to determine if they can be used to further refine risk-based therapy, to reduce therapy for patients predicted to fare well with minimal therapy and intensify therapy for those predicted to be at high risk of relapse.

Clinical Manifestations.

NB may develop at any site of sympathetic nervous system tissue. The signs and symptoms of NB reflect the tumor site and extent of disease. Most cases of NB arise in the abdomen, either in the adrenal gland or in retroperitoneal sympathetic ganglia. Usually a firm, nodular mass is palpable in the flank or midline that is causing abdominal discomfort. On plain radiography or CT the mass often contains calcification and hemorrhage. Wilms tumor, another common flank mass in a young child, usually does not calcify. NB originates from cervical, thoracic, or pelvic ganglia in 30% of cases. Metastatic disease can be associated with myriad signs and symptoms, including fever, irritability, failure to thrive, bone pain, bluish subcutaneous nodules, orbital proptosis, and periorbital ecchymoses (Fig. 490–1). The most common sites of metastasis are the long bones and skull, bone marrow, liver, lymph nodes, and skin. Lung metastases are rare, occurring in less than 3% of cases. Prenatal diagnosis of NB is, at times, possible on maternal ultrasound scans.

Less commonly, children present first with neurologic signs and symptoms. Location in the superior cervical ganglion can result in Horner syndrome. Paraspinal NB can invade the neural foramina, producing symptoms of spinal cord and nerve root compression. Finally, NB can present as a paraneoplastic syndrome of autoimmune origin manifesting as ataxia or **opsomyoclonus** (“dancing eyes and dancing feet”). In such cases, the primary tumor is in the chest or abdomen, and the brain is negative for tumor. Some tumors produce catecholamines that can cause increased sweating and hypertension, and some release vasoactive intestinal peptide, causing a secretory diarrhea. Children younger than 1 yr of age can also present with a unique stage, 4S, that often includes subcutaneous tumor nodules, massive liver involvement, and a small primary tumor without bone involvement.

TABLE 490-1 -- **Neuroblastoma Risk Groups**

Risk Group	Survival	INSS Stage	Age	*MYCN* Status	Shimada Histology	DNA Ploidy
Low	90–100%	1	All	Any	Any	Any
		2	<1 yr	Any	Any	Any
		2	>1 yr	Any	Favorable	
		4S	<1 yr	<10 copies	Favorable	Hyperdiploid
Average	75–98%	3	>1 yr	<10 copies	Favorable	
		3 and 4	<1 yr	<10 copies	Any	Any
		4S	<1 yr	<10 copies	Unfavorable	Any
		4S	<1 yr	<10 copies	Any	Diploid
High	20–60%	2	>1 yr	Any	Unfavorable	
		3	All	>10 copies	Any	
		4	<1 yr	>10 copies	Any	Any
		4	>1 yr	Any	Any	

Figure 490-1 Periorbital metastases of neuroblastoma, with proptosis and ecchymoses.

Diagnosis.

NB is generally discovered as a mass or multiple masses on plain radiographs, CT, or MRI (Fig. 490–2). Tumor markers, including elevated homovanillic acid (HVA) and vanillylmandelic acid (VMA) in urine, are elevated in 95% of cases and help to confirm the diagnosis. A pathologic diagnosis is established from tumor tissue obtained by biopsy. NB can be diagnosed in a typical presentation without a primary tumor biopsy if the patient has neuroblasts observed in bone marrow (Fig. 490–3) and elevated VMA or HVA in the urine.

Evaluation for metastatic disease should include bone scan to detect cortical bone involvement and bone marrow aspirates and biopsies to detect marrow disease. The clinical extent of disease and age, together with cytogenetic and molecular markers performed on the tumor tissue, are used to estimate the prognosis and for determination of risk-directed therapy. Although several staging systems have been used, the International Neuroblastoma Staging System (INSS) is universally used. In the INSS, stage 1 includes tumors confined to the organ or structure of origin. Stage 2 tumors extend beyond the structure of origin but not across the midline, with (stage 2B) or without (stage 2A) ipsilateral lymph node involvement. Stage 3 tumors extend beyond the midline, with or without bilateral lymph node involvement. Stage 4 tumors are disseminated to distant sites (e.g., bone, bone marrow, liver, distant lymph nodes, other organs). Stage 4S refers to children younger than 1 yr of age with dissemination to liver, skin, or bone marrow without bone involvement and with a primary tumor that would otherwise be stage 1 or 2.

Treatment.

The most important clinical and biologic prognostic factors currently used to determine treatment are the age of the patient at diagnosis, stage, *MYCN* status, Shimada histology, and ploidy for infants (see Table 490–1). The prognoses shown are the best published survival rates with recently published therapies (see references). Treatment of low-risk NB is usually surgery for stages 1 and 2 and observation for stage 4S. Even in stage 2 with small amounts of residual tumor, the cure rate is over 90% without further therapy. Furthermore, treatment with chemotherapy or radiation for the rare child with local recurrence can still be curative. Children with spinal cord compression at diagnosis may also require urgent therapy with chemotherapy, surgery, or radiation to avoid neurologic damage. Stage 4S also has a favorable prognosis, with nearly 100% survival with supportive care only, because the tumor regresses spontaneously. Chemotherapy or resection of the primary tumor does not improve survival. Infants younger than 2 months old with stage 4S are at more risk if they have massive liver involvement and respiratory compromise. In such infants, low-dose cyclophosphamide or very low-dose hepatic radiation may be recommended to alleviate symptoms. For

Figure 490-2 *Top,* CT of a thoracic neuroblastoma with intraspinal extension at diagnosis. *Middle*, CT of adrenal primary with extensive lymph node involvement. *Bottom*, Bone scintigraphy with technetium diphosphonate demonstrating diffuse skeletal involvement.

children with stage 4S NB who require treatment for symptoms, the survival rate is 81%.

Treatment of intermediate-risk NB includes surgery, chemotherapy, and, in some cases, radiation. The chemotherapy usually includes moderate doses of cisplatin or carboplatin, cyclophosphamide, etoposide, and doxorubicin given for several months. Radiotherapy is utilized for incomplete response of the tumor to chemotherapy. Children with stage 3 and infants

Figure 490-3 Neuroblastoma cells aspirated from the bone marrow. Clumps of cells often contain three or more cells with or without evidence of rosette formation. Rosettes of cells surrounding an inner mass of fibrillary material are characteristic of neuroblastoma.

younger than 12 mo of age with stage 4 and favorable characteristics have an excellent prognosis of more than 90% survival with this moderate treatment. In this intermediate-risk group, obtaining adequate diagnostic material for determination of Shimada pathologic classification system and for *MYCN* amplification is critical so that children with unfavorable characteristics can receive more aggressive treatment and those with favorable features can be spared excessive toxic therapy.

Treatment of high-risk NB (see Table 490–1) is usually induction chemotherapy followed by high-dose chemotherapy and autologous bone marrow or stem cell transplantation (BMT). A randomized study performed nationally showed significantly improved survival with BMT compared with chemotherapy without BMT. The addition of *cis*-retinoic acid after BMT for 1 yr further improved the 5-yr event-free survival to 50% compared with 20% for those treated with chemotherapy without BMT or *cis*-retinoic acid. However, better therapy is needed for the majority of patients with high-risk NB. New therapies currently under investigation include new chemotherapeutic agents, high-dose chemotherapy with multiple stem cell rescues, monoclonal antibodies combined with growth factors, and antitumor vaccines. It is also hoped that biologic studies of NB will eventually lead to new genetic targets for therapy.

Chapter 491 - Neoplasms of the Kidney

Norman Jaffe
Vicki Huff

WILMS TUMOR

Epidemiology.

Wilms tumor, also designated **nephroblastoma,** is a complex mixed embryonal neoplasm of the kidney composed of three elements: blastema, epithelia, and stroma. The incidence is approximately 8 cases/million children younger than 15 yr of age. It usually occurs in children between 2–5 yr of age, although it has also been encountered in neonates, adolescents, and adults. It comprises approximately 6% of pediatric cancers and is the second most common malignant abdominal tumor in childhood. It may arise in one or both kidneys; the incidence of bilateral Wilms tumor is 7%. It may be associated with hemihypertrophy, aniridia, and other congenital anomalies, usually of the genitourinary tract. It has also been described in association with a variety of syndromes.

Pathogenesis.

The majority of Wilms tumors cases are sporadic, although 1–2% of patients have a family history. Familial predisposition to Wilms tumor is inherited in an autosomal dominant manner. Familial cases are associated with a decreased age at diagnosis and an increased frequency of bilateral disease, although these features are not observed in all families. Congenital anomalies are absent in most families.

One Wilms tumor gene, *WT1*, located at 11p13, has been isolated. *WT1* encodes a zinc finger transcription factor that is critical for normal kidney development. Roughly 20% of all Wilms tumors carry *WT1* mutations, and most of these mutations are tumor specific. Wilms tumor patients with associated congenital anomalies frequently carry germline *WT1* mutations. Familial predisposition to Wilms tumor is usually not associated with *WT1* alterations; familial predisposition genes have been localized to 19q13 and 17q.

Histologically, two broad categories have been recognized: favorable and unfavorable. The favorable type is considered to be the “conventional” form and usually carries a good prognosis. It is characterized by blastema, epithelia, and stromal elements devoid of ectopia or anaplasia. Small amounts of sarcomatous elements in the stroma in an otherwise favorable type apparently do not adversely influence the prognosis. The unfavorable subtype is characterized by marked enlargement of the nuclei, hyperchromatism of the enlarged nuclei, and multipolar mitotic figures. Areas of anaplasia may be focal or diffuse and predict probable high rates of tumor relapse and death. It tends to occur in older, nonwhite patients. Clear cell sarcoma is a subtype of the unfavorable form and usually metastasizes to bone. Rhabdoid tumor, which may metastasize to the brain, is no longer classified as a subtype of Wilms tumor.

Nodal or other potential metastatic sites are usually the most fruitful areas to identify anaplasia, which is extremely uncommon in children younger than 2 yr of age. A high index of suspicion and more thorough sampling of techniques are appropriate if anaplasia is detected, particularly in older children. The phenomenon is generally not found once chemotherapy has been administered. Anaplasia related to skeletal muscle cells does not appear to be associated with an increased incidence of relapse.

Recent studies have shown a remarkable correlation among the DNA content in the cells of Wilms tumor, histiologic subtype, and treatment outcome. Stem lines of both the primary tumor and metastases are in the diploid and low aneuploid (hyperdiploid) range. Tumors with hyperdiploid content are also characteristic of the anaplastic (unfavorable) varieties and

have enormous complex translocations. They respond poorly to chemotherapy.

CONGENITAL ABNORMALITIES.

Several syndromes, congenital abnormalities, and chromosomal aberrations are commonly reported in Wilms tumor (Tables 491–1 and 491–2). **WAGR syndrome** comprises Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation. Patients with this syndrome have a constitutional deletion of chromosome 11p13 where both the Wilms tumor gene, *WT1,* and the aniridia gene, *PAX6,* are located. **Denys-Drash syndrome** comprises male pseudohermaphrodism, early-onset renal failure characterized by mesangial sclerosis, and an increased risk of Wilms tumor. Patients with this syndrome typically carry a point mutation within the *WT1* gene. The **Beckwith-Wiedemann syndrome** is characterized by hemihypertrophy, macroglossia, and visceromegaly, with a risk of developing Wilms tumor of 3–5%. A variety of 11p15.5 abnormalities have been reported in patients with this syndrome, and it is postulated that a second Wilms tumor gene, *WT2,* is located in this region. Other syndromes or conditions with an increased risk of Wilms tumor include hemihypertrophy, aniridia, genitourinary anomalies, Pearlman syndrome, Sotos syndrome, neurofibromatosis (von Recklinghausen disease), and von Willebrand disease. The most common genitourinary anomalies associated with Wilms tumor are hypoplasia, fusion and ectopia of the kidney, duplications of the collecting systems, hypospadias, and cryptorchidism.

Clinical Manifestations.

Wilms tumor usually presents as an abdominal mass. It is generally discovered fortuitously, and it is not uncommon for it to be brought to the mother's attention while bathing the infant. It may also be identified during a well-child clinical examination. Renal masses of this type are usually smooth and firm and occasionally may cross the midline. They vary in size. Some patients may present with abdominal pain and vomiting and, infrequently, hematuria. Hypertension has also been described and is probably due to renal ischemia. Occasionally, rapid abdominal enlargement and anemia may occur owing to bleeding into the renal parenchyma or pelvis. Hematuria has been reported in 12–25% of patients.

Diagnosis.

Any abdominal mass in a child must be considered malignant until diagnostic imaging and laboratory findings define its true nature. If there is any doubt, biopsy or excision and histologic verification is the final arbiter. Wilms tumor must be differentiated from a variety of malignant abdominal and pelvic tumors (Table 491–3). Once an abdominal mass is discovered

TABLE 491-1 -- **Syndromes Associated with Wilms Tumor and Their Clinical and Genetic Characteristics**

Syndrome	Clinical Characteristics	Chromosome or other abnormalities
WAGR	Aniridia, genitourinary abnormalities, mental retardation	Del 11p13 (*WT1* & *PAX6* loci)
Denys-Drash	Early-onset renal failure with renal mesangial sclerosis, male pseudohermaphrodism, increase risk of Wilms tumor	*WT1* mutations
Beckwith-Wiedemann	Organomegaly (liver, kidney, adrenal, pancreas), macroglossia omphalocele, hemihypertrophy	Uniparental paternal disomy, duplication 11p15.5, loss of imprinting, mutation of p57KIP57 have been described. Del 11p15.5 (*WT2* locus)
		May also involve *IGF2* and/or *H19* genes

TABLE 491-2 -- **Genetic Alterations Observed in Wilms Tumors**

Gene	Wilms Tumor Characteristic	Frequency	Type of Alteration
WT1	Unselected	~20%	Deletions, truncating mutations, missense mutations in zinc finger–encoding exons
ß-Catenin	Unselected	~15%	Missense mutations or deletions affecting protein phosphorylation sites
	Tumors with *WT1* mutations (~20% of total)	~50%	
P53	Anaplastic histology (~5% of total)	~80%	Missense and truncating mutations

, a complete physical examination should be performed followed by a complete blood cell count, liver and kidney function studies, and a search for specific tumor markers secreted by the suspected tumor. Imaging studies include a flat plate of the abdomen, ultrasonography, and CT and/or MRI.

CT scan permits confirmation of the intrarenal origin of the mass. It may also provide information on the extent of tumor, involvement of the inferior vena cava, and integrity of the contralateral kidney. Tumors enhance slightly after injection of contrast medium, which is useful to determine the function of the uninvolved kidney in the event that nephrectomy is required. MRI may also help define the extent of tumor. Ultrasonography may also contribute to identification of the tumor and integrity of the inferior vena cava. Occasionally, angiography may be requested to plan the surgical procedure. Bone scans are obtained for clear cell sarcoma of the kidney and MRI or CT of the brain in a malignant rhabdoid tumor.

Radiographic examination of the chest is required to determine the presence of pulmonary metastases. Pulmonary metastases from Wilms tumor can generally be identified on conventional radiograph; therefore, CT scans of the lungs are not routinely obtained. Occasionally, a CT scan demonstrates isolated nodules in patients with normal chest radiographs; the true nature of these nodules is uncertain.

STAGING.

The staging system frequently utilized was developed by the National Wilms Tumor Study Group (Table 491–4) and correlates with prognosis (Table 491–5). Stage I Wilms tumor is confined to the kidney and, by definition, is completely excised with the capsular surface intact. Stage II Wilms tumor is also confined to the kidney, although the capsule is penetrated or tumor is present in the perirenal soft tissue. Stage III Wilms tumor has postsurgical residual nonhematogenous extension present. Spread is confined to the abdomen and may involve the perirenal bed, draining lymph nodes, or the surrounding tissue and organs by contiguity. Stage IV Wilms tumor is characterized by hematogenous metastases. The metastases generally involve the lungs and occasionally the liver. Stage V Wilms tumor is designated by bilateral renal involvement.

Treatment.

Surgical extirpation of the tumor should be performed. The patency of the inferior vena cava should be established before the resection; if it is not patent, preoperative chemotherapy should be administered. During the operation the contralateral kidney should be examined to exclude bilateral Wilms tumor. The liver should be inspected for possible metastases

TABLE 491-3 -- Differential Diagnosis of Abdominal and Pelvic Tumors in Infants and Children

Tumor	Age	Clinical Signs	Laboratory Findings
Wilms tumor	Preschool	Unilateral flank mass, aniridia, hemihypertrophy	Hematuria; bone scintigraphy (clear cell sarcoma)
Neuroblastoma	Preschool	Gastrointestinal/ genitourinary obstruction, raccoon eyes, myoclonus-opsoclonus, diarrhea, skin nodules (infants)	Increased VMA; increased HVA; increased ferritin; stippled calcification in mass. Bone marrow +
Non-Hodgkin lymphoma	>1 yr	Intussusception in >2-yr-old child	Increased urate; bone marrow +
Rhabdomyosarcoma	All	Gastrointestinal/genitourinary obstruction, sarcoma botryoides, vaginal bleeding, paratesticular mass	
Germ cell/teratoma	Preschool, teens	Girls: abdominal pain, vaginal bleeding	Increased hCG;
		Boys: testicular mass, new onset “hydrocele”	Increased AFP
		Sacrococcygeal mass/dimple	
Hepatoblastoma	Birth–3 yr	Large, firm liver	Increased AFP
Hepatoma	School age, teens	Large, firm liver; hepatitis B, cirrhosis	Increased AFP

VMA = vanillylmandelic acid; HMA = homovanillic acid; hCG = human chorionic gonadotropin; AFP = a-fetoprotein.

TABLE 491-4 -- Staging System Developed by the Third National Wilms Tumor Study Group

Stage I	Tumor limited to kidney and is completely excised. Capsular surface intact; no tumor rupture; no residual tumor apparent beyond margins of excision
Stage II	Tumor extends beyond kidney but is completely excised. Regional extension of tumor; vessel infiltration; tumor biopsied or local spillage of tumor confined to the flank. No residual tumor apparent at or beyond margins of excision
Stage III	Residual nonhematogenous tumor confined to the abdomen. Lymph node involvement of hilus, periaortic chains, or beyond; diffuse peritoneal contamination by tumor spillage; peritoneal implants of tumor; tumor extends beyond surgical margins microscopically or macroscopically; tumor not completely removable because of local infiltration into vital structures
Stage IV	Deposits beyond stage III (e.g., lung, liver, bone, brain)
Stage V	Bilateral renal involvement at diagnosis

, although CT, MRI, or ultrasonography may have identified metastases preoperatively. The retroperitoneal lymph nodes should be examined and suspicious nodes sampled for tumor involvement. Every attempt should be made to avoid spillage of tumor.

Most centers utilize chemotherapy guidelines provided by the National Wilms Tumor Study Group. For stage I and II, favorable histology tumors, vincristine and dactinomycin are administered. For stage III, favorable histology, vincristine, dactinomycin, and doxorubicin are administered. Radiation therapy is also administered to the tumor bed. In stage IV, favorable histology, vincristine, dactinomycin, and doxorubicin are administered. In addition, radiation therapy is administered to the sites of known disease, particularly the lungs. If tumor in the liver is present, surgical resection as opposed to radiation therapy may be considered. Resistant tumors that fail to respond to chemotherapy and radiation, or tumors that recur, may be considered for surgical resection and alternate (investigational) chemotherapy.

In the unfavorable histology subtype, vincristine, dactinomycin, doxorubicin, and cyclophosphamide are administered. Treatment is more aggressive and usually incorporates radiation therapy to the tumor bed and sites of established metastases. Clear cell sarcoma of bone has responded to a combination of cisplatin, doxorubicin, and radiation therapy. Additional therapy with cyclophosphamide or ifosfamide may also be considered.

INOPERABLE WILMS TUMOR.

Chemotherapy is administered for all Wilms tumors that appear inoperable. In these circumstances the diagnosis is usually established by percutaneous needle biopsy. The selection of chemotherapy is dictated by histologic criteria: for favorable histologic subtypes, vincristine and dactinomycin are utilized for stages I and II and vincristine, dactinomycin, and doxorubicin for stages III and IV. Tumors of the unfavorable variety are treated with vincristine, dactinomycin, doxorubicin, and cyclophosphamide. In most instances a reduction in tumor size will be obtained. The prognosis for inoperable tumors treated with chemotherapy, surgery, and, if required, radiation therapy is generally favorable, with survival rates of more than 50%.

BILATERAL WILMS TUMOR.

Chemotherapy for bilateral Wilms tumor is identical to that employed for inoperable tumors and is utilized to render the tumor amenable to surgical extirpation. This may comprise unilateral nephrectomy and contralateral partial nephrectomy or bilateral partial nephrectomies. These maneuvers permit ablation of viable neoplasm and conservation of renal tissue. Surgical procedures are dictated by the extent of tumor and response to chemotherapy. Postoperatively, chemotherapy and, not infrequently, radiation therapy are administered. Occasionally, preoperative radiation is also utilized. These therapeutic strategies have yielded survival rates of 60–85%.

SALVAGE CHEMOTHERAPY.

Patients may relapse during or after treatment with conventional therapy. Such patients, particularly those with favorable hematology, can often be salvaged with alternate treatment. In these circumstances, combination chemotherapy with vincristine, doxorubicin (Adriamycin), cyclophosphamide, and dactinomycin (Actinomycin D) (VACA) or ifosfamide, carboplatin, and etoposide (ICE) may be attempted. High-dose chemotherapy with bone marrow rescue has also been employed. A multidisciplinary strategy with surgery, radiation therapy, and chemotherapy will generally yield the best result.

Prognosis.

Major prognostic factors are tumor size, stage, and histology (see Table 491–5). The prognosis is worse in patients with a larger tumor (>500?g), advanced stage (III and IV), and unfavorable histologic subtype. Nonetheless, Wilms tumor constitutes a paradigm of successful multidisciplinary treatment; more than 60% of patients with all stages generally survive. Stages I through III have a cure rate varying from 88–98%.

TABLE 491-5 -- Wilms Tumor: Survival by Histology and Stage

Histology/Stage	Survival 2 Yr (%)	Survival 4 Yr (%)
Favorable I	98	97
Favorable II	96	94
Favorable III	91	88
Favorable IV	88	82
Anaplastic I	89	89
Anaplastic II–IV	56	54

Modified from Wilms' tumor: Status report, 1990. By the National Wilms' Tumor Study Committee. J Clin Oncol 1991;9:877–87.

OTHER KIDNEY TUMORS IN CHILDREN

Congenital Mesoblastic Nephroma.

This is a unique congenital neoplasm of the infant kidney that rarely metastasizes. It occurs more often in males and has been noted to produce renin. The tumor is a massive, firm, infiltrative, solitary renal mass. Grossly and microscopically it resembles a leiomyoma or a low-grade leiomyosarcoma with trapped nephrons. Microscopy reveals fibroblast or myofibroblast cells. The tumor accounts for the majority of congenital renal tumors. Most cases are considered benign, and there is division of opinion regarding the utility of chemotherapy. One report noted that vincristine and dactinomycin administered as adjuvant therapy did not prevent metastases. In another report, metastatic disease apparently responded to vincristine, doxorubicin, and cyclophosphamide.

Nephroblastomatosis.

Nephroblastomatosis generally refers to the abnormal persistence of embryonal renal tissue that may be associated with the development of Wilms tumor. It has been suggested that a brief course of relatively nontoxic chemotherapy (vincristine and dactinomycin) may be beneficial by reducing the large volume of the kidneys. Persistent nodule renal blastema and associated nephroblastic abnormalities appear to remain in the kidneys of many, if not all, treated patients despite the reduction in renal volume. The favorable survival and response rate of bilateral Wilms tumor suggests a strong relationship of the latter to the nodular renal blastema nephroblastomatosis complex. Nephrogenic nests detected in one kidney should prompt a careful evaluation of the contralateral kidney. Radiographic follow-up with CT may also be indicated. Whether chemotherapy can reduce the incidence of development of subsequent Wilms tumor is unknown.

Multicystic Nephroblastoma.

Tumors of the kidney may occasionally contain cysts, some of which may be linked to Wilms tumor. There is a melange of diagnostic terms applied to such tumors,

including cystic partially differentiated nephroblastoma (CPDN), polycystic nephroblastoma, and multilocular nephroma. The majority of the reported cases of multicystic nephroblastoma occur in patients younger than 1 yr of age. When confronted with this type of tumor biology, a benign process may be considered to be present. However, if there is definite evidence of Wilms tumor, treatment with chemotherapy is justified.

Renal Cell Carcinoma.

The tumor is rare in the first decades of life, but it has occasionally been reported in children and teenagers. It usually presents as an abdominal mass and/or hematuria. Complete resection may achieve cure. Occasionally, adjuvant treatment with interferon and 5-fluorouracil has been recommended.

Chapter 492 - Soft Tissue Sarcomas

Carola A. S. Arndt

Soft tissue sarcomas occur with an annual incidence of 8.4 cases/million white children younger than 15 yr of age. The incidence in black children is 50% of that in white children. Rhabdomyosarcoma accounts for more than half of soft tissue sarcomas. The prognosis most strongly correlates with extent of disease at diagnosis, primary tumor site, and type of treatment.

RHABDOMYOSARCOMA

Epidemiology.

The most common pediatric soft tissue sarcoma, rhabdomyosarcoma, accounts for 5–8% of childhood cancers. These tumors occur at virtually any anatomic site but are most often found in the head and neck (40%), genitourinary tract (20%), extremities (20%), and trunk (10%); retroperitoneal and other sites account for the remainder of primary sites. The primary anatomic site is related to both age and tumor histology. Extremity lesions are more likely to occur in older children and to have alveolar histology. Rhabdomyosarcoma occurs with increased frequency in patients with neurofibromatosis and has been associated with maternal breast cancer in the Li-Fraumeni syndrome, suggesting a genetic influence.

Pathogenesis.

Rhabdomyosarcoma is thought to arise from the same embryonic mesenchyme as striated skeletal muscle. On the basis of light microscopic appearance, it belongs to the group of small round cell tumors that includes Ewing sarcoma, neuroblastoma, and non-Hodgkin lymphoma. Definitive diagnosis of a pathologic specimen may require immunohistochemical studies using antibodies to skeletal muscle (e.g., desmin, muscle-specific actin, and Myo-D) and electron microscopy.

Determination of the specific histologic subtype is important in treatment planning and assessment of prognosis. There are four recognized histologic subtypes. The **embryonal type** accounts for about 60% of all cases and has an intermediate prognosis. The **botryoid type**, a variant of the embryonal form in which tumor cells and an edematous stroma project into a body cavity like a bunch of grapes, accounts

for 6% of cases and is most often found in the vagina, uterus, bladder, nasopharynx, and middle ear. **Alveolar tumors**, which account for about 15% of cases, are often characterized by 2;13 or 1;13 chromosomal translocations. The tumor cells tend to grow in cores that often have cleftlike spaces resembling alveoli. Alveolar tumors occur most often in the trunk and extremities and carry the poorest prognosis. The **pleomorphic type (adult form)** is rare in childhood (1% of cases). About 20% of retinoblastomas are considered to be **undifferentiated sarcomas**.

Clinical Manifestations.

The most common presenting feature is a mass that may or may not be painful. Symptoms are caused by displacement or obstruction of normal structures. Origin in the nasopharynx may be associated with nasal congestion, mouth breathing, epistaxis, and difficulty with swallowing and chewing. Regional extension into the cranium can produce cranial nerve paralysis, blindness, and signs of increased intracranial

pressure with headache and vomiting. When the tumor develops in the face or cheek, there may be swelling, pain, trismus, and, as extension occurs, paralysis of cranial nerves. Tumors in the neck can produce progressive swelling with neurologic symptoms after regional extension. Orbital primary tumors are usually diagnosed early in their course because of associated proptosis, periorbital edema, ptosis, change in visual acuity, and local pain. When the tumor arises in the middle ear, the most common early signs are pain, hearing loss, chronic otorrhea, or a mass in the ear canal; extensions of tumor produce cranial nerve paralysis and signs of an intracranial mass on the involved side. An unremitting croupy cough and progressive stridor can accompany rhabdomyosarcoma of the larynx. Because most of these signs and symptoms are also associated with common childhood conditions, clinicians must be alert to the possibility of tumor.

Rhabdomyosarcoma of the trunk or extremities is often first noticed after trauma and may be regarded initially as a hematoma. When the swelling does not resolve or increases, malignancy should be suspected. Involvement of the genitourinary tract can produce hematuria, obstruction of the lower urinary tract, recurrent urinary tract infections, incontinence, or a mass detectable on abdominal or rectal examination. Paratesticular tumors usually present as a painless, rapidly growing mass in the scrotum. Vaginal rhabdomyosarcoma may present as a grapelike mass of tumor tissue bulging through the vaginal orifice **(sarcoma botryoides)** and can cause urinary tract or large bowel symptoms. Vaginal bleeding or obstruction of the urethra or rectum may occur. Similar findings can be noted with uterine primaries.

Tumors in any location may disseminate early, with presenting symptoms of pain or respiratory distress associated with pulmonary metastases. Extensive bone involvement can produce symptomatic hypercalcemia. In such cases, it may be difficult to identify the primary lesion.

Diagnosis.

Early diagnosis of rhabdomyosarcoma requires a high index of suspicion. The microscopic appearance is that of a small round blue cell tumor. Neuroblastoma, lymphoma, and Ewing sarcoma are also small round blue cell tumors. The differential diagnosis depends on the site of presentation. Definitive diagnosis is established by biopsy, microscopic appearance, and immunohistochemical stains. A lesion in an extremity may be thought to be a hematoma or hemangioma, an orbital lesion resulting in proptosis may be treated as an orbital cellulitis, or bladder obstructive symptoms may be missed. Paratesticular lesions may be ignored for a long time by adolescents. Unfortunately, several months often elapse between the initial symptoms and biopsy. Diagnostic procedures are determined mainly by the area of involvement. MRI or CT is necessary for evaluation of the primary tumor site. With signs and symptoms in the head and neck area, radiographs should be examined for evidence of a tumor mass and for indications of bony erosion. CT scans should be performed to identify intracranial extension and may also reveal bony involvement at the base of the skull; this may be difficult to visualize. For abdominal and pelvic tumors, ultrasound examination and CT with oral and intravenous contrast media or MRI can help delineate the tumor. Figure 492–1 shows a CT scan of the pelvis in a child with a bladder rhabdomyosarcoma. A radionuclide bone scan, chest CT scan, and bilateral bone marrow aspirate and biopsy should be performed to evaluate the patient for the presence of metastatic disease. The results of these studies are used to plan treatment. The most essential element of the diagnostic workup is examination of tumor tissue, which includes the use of special histochemical stains and immunostains. Lymph nodes should be sampled also for presence of disease spread, especially in extremity tumors.

Treatment.

Patients with completely resected tumors have the best prognosis. Unfortunately, most rhabdomyosarcomas are not completely resectable. At the initial surgery, tumor margins should be carefully defined and an appropriate search for regional or metastatic disease (e.g., to regional lymph nodes or adjacent structures) should be completed even if the procedure is limited to biopsy. Treatment is based on the primary tumor location and disease stage (“clinical group”). Most patients are given preoperative chemotherapy in an attempt to reduce the extent of surgery required and to preserve vital organs, particularly in the genitourinary tract. For patients with group I tumors, complete local excision is followed by chemotherapy to reduce the likelihood of subsequent metastatic disease. For patients with group II tumors (microscopic residual tumor), surgery is followed by local irradiation and systemic multiagent chemotherapy. Patients with group III tumors (gross residual tumor) receive initial systemic multiagent chemotherapy, followed by irradiation and surgery if possible. Children with metastatic (group IV) rhabdomyosarcoma are treated principally with systemic chemotherapy and irradiation. Standard chemotherapeutic agents include vincristine, dactinomycin,

Figure 492-1 CT scan of pelvis in a patient with an embryonal rhabdomyosarcoma of the bladder.

TABLE 492-1 -- **Features of Most Common Types of Nonrhabdomyocarcoma Soft Tissue Sarcomas**

Tissue Type	Tumor	Natural History and Biology
Adipose	Liposarcoma	A very rare tumor. Usually arises in the extremities or retroperitoneum; associated with a nonrandom translocation, t(12; 16) (q13; p11). Tends to be locally invasive and rarely metastasizes; wide local excision is the treatment of choice. The role of radiation therapy and chemotherapy in treating gross residual or metastatic disease is not established.
Fibrous	Fibrosarcoma	Most common soft tissue sarcoma in children younger than 1 yr. Congenital fibrosarcoma is a low- grade malignancy that commonly arises in the extremities or trunk and rarely metastasizes. Surgical excision is treatment of choice; dramatic responses to preoperative chemotherapy may occur. In children older than 4 yr, the natural history is similar to that in adults (a 5- yr survival rate of 60%); wide surgical excision and preoperative chemotherapy are commonly used.
	Malignant fibrous histiocytoma	Most commonly arises in the trunk and extremities, deep in the subcutaneous layer. Histologically subdivided into storiform, giant cell, myxoid, and angiomatoid variants. The angiomatoid type tends to affect younger patients and is curable with surgical resection alone. Wide surgical excision is the treatment of choice. Chemotherapy has produced objective tumor regressions.
Vascular	Hemangiopericytoma	Often arises in the lower extremities or retroperitoneum; may present with hypoglycemia and hypophosphatemic rickets. Both benign and malignant histology. Nonrandom translocations t(12; 19) (q13; q13) and t(13; 22) (q22; q11) have been described. Complete surgical excision is the treatment of choice. Chemotherapy and radiotherapy may produce responses.
	Angiosarcoma	Rare in children; 33% arise in skin, 25% in soft tissue, and 25% in liver, breast, or bone. Associated with chronic lymphedema and exposure to vinyl chloride in adults. Survival rate is poor (12% at 5 yr) despite some responses to chemotherapy/ radiotherapy.
	Hemangioendothelioma	Can occur in soft tissue, liver, and lung. Localized lesions have a favorable outcome; lesions in lung and liver are often multifocal and have a poor prognosis.
Peripheral nerves	Neurofibrosarcoma	Also known as the malignant peripheral nerve sheath tumor. Develops in up to 16% of patients with NF1; almost 50% occur in patients with NF1. Deletions of chromosome 22q11- q13 or 17q11 and p53 mutations have been reported. Commonly arises in trunk and extremities and is usually locally invasive. Complete surgical excision is necessary for survival; response to chemotherapy is suboptimal.
Synovium	Synovial sarcoma	The most common NRSTS in some series. Often presenting in the 3rd decade, but 33% of patients are younger than 20 yr. Typically arises around the knee or thigh and is characterized by a nonrandom translocation t(X; 18) (p11; q11). Wide surgical excision is necessary. Radiotherapy is effective in microscopic residual disease, and ifosfamide-based therapy is active in advanced disease.
Unknown	Alveolar soft part sarcoma	Slow- growing tumor; tends to recur or metastasize to lung and brain years after diagnosis. Often arises in the extremities and head and neck. A myogenic origin has been proposed. Resection of primary and metastatic sites, when possible, is recommended.
Smooth muscle	Leiomyosarcoma	Often arises in the gastrointestinal tract and may be associated with a t(12; 14) (q14; q23) translocation. Associated with Epstein- Barr virus in immunodeficiency syndromes (including AIDS). Complete surgical excision is the treatment of choice.

N

NF = Neurofibromatosis; NRSTS = nonrhabdomyosarcoma soft tissue sarcoma.

and cyclophosphamide. Topotecan is being evaluated in therapeutic trials.

Prognosis.

Among patients with resectable tumor, 80–90% have prolonged, disease-free survival. Unresectable tumor localized to certain "favorable" sites (e.g., the orbit) also has a high likelihood of cure. About 70% of patients with incompletely resected tumor also achieve long-term disease-free survival. Patients with disseminated disease have a poor prognosis; only about half achieve remission, and fewer than half of these are cured. Older children have a poorer prognosis than younger ones. For all patients, surveillance for late effects of cancer treatment, such as impaired bone growth due to radiation, sterility from cyclophosphamide, and second malignancies, is important.

OTHER SOFT TISSUE SARCOMAS

The nonrhabdomyosarcoma soft tissue sarcomas (NRSTS) constitute a heterogeneous group of tumors that account for 3% of all childhood malignancies. Because they are relatively rare in children, much of the information about their natural history and treatment has been derived from studies of adult patients. In children, the median age at diagnosis is 12 yr of age and males predominate (male:female ratio 2.3:1). The most common histologic types are synovial sarcoma (42%), fibrosarcoma (13%), malignant fibrous histiocytoma (12%), and neurogenic tumors (10%). Table 492–1 describes the clinical features, treatment, and prognosis of the most common NRSTS. These tumors commonly arise in the trunk or lower extremities. Tumor size, stage (clinical group), invasiveness, and histologic grade correlate with survival.

Surgery remains the mainstay of therapy, but a careful search for lung and bone metastases should be undertaken before surgical excision. Lymph node spread is rare, and routine dissection is not recommended. Chemotherapy and radiotherapy should be considered for large, high-grade, and unresectable tumors. The role of chemotherapy in nonrhabdomyosarcomatous tumors is not as well defined as in rhabdomyosarcoma. Patients with unresectable or metastatic disease are treated with multiagent chemotherapy in addition to radiation and/or surgery.

Chapter 493 - Neoplasms of Bone

Carola A. S. Arndt

493.1 Malignant Tumors of Bone

The annual incidence of malignant bone tumors in the United States is approximately 7 cases/million white children younger than 15 yr of age, with a slightly lower incidence in black children. Osteosarcoma is the most common primary malignant bone tumor in children and adolescents, followed by Ewing sarcoma (Table 493–1 and Fig. 493–1). In children younger than 10 yr of age, Ewing sarcoma is more common than osteosarcoma. Both tumor types occur most frequently in the 2nd decade of life.

OSTEOSARCOMA

Epidemiology.

The annual incidence of osteosarcoma in the United States is 5.6 cases/million children younger than 15 yr of age. The highest risk period for development of osteosarcoma is during the adolescent growth spurt, which suggests an association between rapid bone growth and malignant transformation. Patients with osteosarcoma are taller than their peers of similar age.

Pathogenesis.

Although the cause of osteosarcoma is unknown, certain genetic or acquired conditions predispose patients to development of osteosarcoma. Patients with hereditary retinoblastoma have a significantly increased risk of developing osteosarcoma. The sites of osteosarcoma in these patients were initially thought to be in previously irradiated areas; however, they have since been shown to arise in sites far from the radiation field. Predisposition to development of osteosarcoma in these patients is thought to be related to loss of heterozygosity of the *RB* gene. Osteosarcoma also occurs in the **Li-Fraumeni syndrome**, which is a familial cancer syndrome associated with germline mutations of the *TP53* gene. Kindreds with Li-Fraumeni syndrome have a spectrum of malignancies in 1st-degree relatives, including carcinoma of the breast, soft tissue sarcomas, brain tumors, leukemia, adrenal cortical carcinoma, and other malignancies. **Rothmund-Thomson syndrome** is a rare syndrome associated with short stature, skin telangiectasia, small hands and feet, hypoplastic or absent thumbs, and a high risk of osteosarcoma. Osteosarcoma can also be induced by irradiation for Ewing sarcoma, craniospinal irradiation for brain tumors, or high-dose irradiation for other malignancies. Other benign conditions that can be associated with malignant

TABLE 493.1-1 -- **Comparison of Features of Osteosarcoma and the Ewing Family of Tumors**

Feature	Osteosarcoma	Ewing Family of Tumors
Age	Second decade	Second decade
Race	All races	Primarily whites
Sex (M:F)	1.5:1	1.5:1
Cell	Spindle cell–producing osteoid	Undifferentiated small round cell, probably of neural origin
Predisposition	Retinoblastoma, Li-Fraumeni syndrome, Paget's disease, radiotherapy	None known
Site	Metaphyses of long bones	Diaphyses of long bones, flat bones
Presentation	Local pain and swelling; often history of injury	Local pain and swelling; fever
Radiographic findings	Sclerotic destruction (less commonly lytic); sunburst pattern	Primarily lytic, multilaminar periosteal reaction (“onion skinning”)
Differential diagnosis	Ewing's sarcoma, osteomyelitis	Osteomyelitis, eosinophilic granuloma, lymphoma, neuroblastoma, rhabdomyosarcoma
Metastasis	Lungs, bones	Lung, bones
Treatment	Chemotherapy	Chemotherapy
	Ablative surgery of primary tumor	Radiotherapy and/or surgery of primary tumor
Outcome	Without metastases: 70% cured; with metastases at diagnosis, = 20% survival	Without metastases: 60% cured; with metastases at diagnosis, 20–30% survival

Figure 493.1-1 *A*, Age and skeletal distribution of 1,649 cases of osteosarcoma in the Mayo Clinic files. *B*, Age and skeletal distribution of 512 cases of Ewing sarcoma in the Mayo Clinic files. (From Unni KK [editor]: *Dahlin's Bone Tumors: General Aspects and Data on 11,087 Cases*, 5th ed.

Philadelphia, Lippincott-Raven, 1996. Reprinted by permission of the Mayo Foundation.)

transformation to osteosarcoma include Paget disease, enchondromatosis, multiple hereditary exostoses, and fibrous dysplasia.

The pathologic diagnosis of osteosarcoma is made by demonstration of a highly malignant, pleomorphic, spindle cell neoplasm associated with the formation of malignant osteoid and bone. There are four pathologic subtypes of conventional high- grade osteosarcoma: osteoblastic, fibroblastic, chondroblastic, and telangiectatic. No significant differences in outcome are associated with the various subtypes, although the chondroblastic component of that subtype may not respond as well to chemotherapy. The role of various genes in prognosis such as drug resistance–related genes, tumor suppressor genes, and genes related to apoptosis is being evaluated.

Telangiectatic osteosarcoma may be confused with aneurysmal bone cyst because of its lytic appearance radiographically. High-grade osteosarcoma typically arises in the diaphyseal region of long bones and invades the medullary cavity. It may also be associated with a soft tissue mass. Two variants of osteosarcoma, parosteal and periosteal osteosarcoma, should be distinguished from conventional osteosarcoma because of their characteristic clinical features. **Parosteal osteosarcoma** is a low-grade, well-differentiated tumor that does not invade the medullary cavity and is most commonly found in the posterior aspect of the distal femur. Surgical resection alone is often curative in this lesion, which has a low propensity for metastatic spread. **Periosteal osteosarcoma** is a rare variant, which arises on the surface of the bone but has a higher rate of metastatic spread than the parosteal type and an intermediate prognosis.

Clinical Manifestations.

Pain and swelling are the most common presenting manifestations of osteosarcoma. Because these tumors occur most frequently in active adolescents, initial complaints may be attributed to a sports injury or sprain; any bone or joint pain not responding to conservative therapy within a reasonable amount of time should be investigated thoroughly. Additional clinical findings may include limitation of motion, joint effusion, tenderness, and warmth. Results of routine laboratory tests, such as a complete blood cell count and chemistry panel, are usually normal, although alkaline phosphatase or lactic dehydrogenase levels may be elevated.

Diagnosis.

The diagnosis of a bone tumor should be suspected in a patient who presents with deep bone pain, often causing nighttime awakening, a palpable mass, and a radiograph demonstrating a lesion. The lesion may be mixed lytic and blastic in appearance, but new bone formation is usually visible. The classic radiographic appearance of osteosarcoma is the **sunburst** pattern (Fig. 493–2). When osteosarcoma is suspected, the patient should be referred to a center with experience in managing bone tumors. The biopsy should be performed by the surgeon who will ultimately perform the definitive surgery so that the incisional biopsy site can be placed in a manner that will not compromise the ultimate limb salvage procedure. Tissue is usually obtained for molecular and biologic studies at the time of the initial biopsy. Before biopsy, MRI of the primary lesion and the entire bone should be performed to evaluate the tumor for its proximity to nerves and blood vessels and soft tissue and joint extension as well as for skip lesions. The metastatic work-up should be performed before biopsy and includes CT of the chest and radionuclide bone scan to evaluate for lung and bone metastases, respectively. The differential diagnosis of a lytic bone lesion includes histiocytosis, Ewing sarcoma, lymphoma, and bone cyst.

Treatment.

The survival of children with nonmetastatic osteosarcoma was only 20% at 5 yr with surgery alone. It is well established that with chemotherapy and surgery, the 5-yr disease-free survival rate of patients with nonmetastatic extremity osteosarcoma is 65–75%. Complete surgical resection of the tumor is important for cure. The current approach is to treat patients with preoperative chemotherapy in an attempt to facilitate limb salvage operations and to immediately treat micrometastatic disease. Up to 80% of patients are able to undergo limb salvage operations after initial chemotherapy. Some institutions use intra-arterial chemotherapy to infuse chemotherapy directly into an artery feeding the tumor, although this has not been proved to be better than conventional intravenous chemotherapy. It is important to resume chemotherapy as soon as possible after surgery. Lung metastases present at diagnosis should be resected by thoracostomies at some time during the course of treatment. Active agents currently in use in multidrug chemotherapy regimens for conventional osteosarcoma include doxorubicin, cisplatin, methotrexate, and ifosfamide. Current national treatment protocols are investigating dose intensification of various agents for patients who have a poor histologic response at time of surgery. After limb salvage surgery, intensive rehabilitation and physical therapy is necessary to ensure maximal functional outcome. For patients who require amputation, early prosthetic fitting and gait training is essential to enable them to resume as normal activities as possible. Before definitive surgery, patients with tumors on weight-bearing bones should be instructed to use

---

Figure 493.1-2 Radiograph of an osteosarcoma of the femur with typical “sunburst” appearance of bone formation.

crutches to avoid stressing the weakened bone and causing a pathologic fracture. The role of chemotherapy in parosteal and periosteal osteosarcoma is not well defined.

Prognosis.

Surgical resection alone is curative only for patients with parosteal osteosarcoma. Conventional osteosarcoma requires multiagent chemotherapy. Up to 75% of patients with nonmetastatic extremity osteosarcoma are cured with current multiagent treatment protocols. Patients with pelvic tumors do not have as favorable a prognosis as those with extremity primaries. From 20–30% of patients who have limited numbers of pulmonary metastases can also be cured with aggressive

chemotherapy and resection of lung nodules. Patients with bone metastases and those with widespread lung metastases have an extremely poor prognosis. Long-term follow-up of patients with osteosarcoma is important to monitor for late effects of chemotherapy such as cardiotoxicity from anthracycline. Patients who develop late isolated lung metastases may be cured with surgical resection alone.

EWING SARCOMA

Epidemiology.

The incidence of Ewing sarcoma is 2.1 cases/million children in the United States. It is extremely rare among black children. Ewing sarcoma, an undifferentiated sarcoma of bone, may also arise from soft tissue. The term **Ewing sarcoma family of tumors** refers to a group of small round cell undifferentiated tumors thought to be of neural crest origin that generally carry the same chromosomal translocation. This family of tumors includes Ewing sarcoma of bone and soft tissue and **peripheral primitive neuroectodermal tumor (PPNET).** Treatment protocols for these tumors are the same whether the tumors arise in bone or soft tissue. Anatomic sites of primary tumors arising in bone are evenly distributed between the extremities and the central axis (pelvis, spine, and chest wall). Primary tumors arising in the chest wall are often referred to as **Askin tumors.**

Pathogenesis.

Immunohistochemical staining assists in the diagnosis of Ewing sarcoma to differentiate it from other small, blue, round cell tumors such as lymphoma, rhabdomyosarcoma, and neuroblastoma. Histochemical stains may react positively with certain neural markers on tumor cells (neuron-specific enolase and S-100), especially in PPNET. Reactivity with muscle markers (e.g., desmin, actin) is absent. Additionally, the cell surface glycoprotein MIC-2 is usually positive. A specific chromosomal translocation, t(11;22), or a variant thereof is found in most of the Ewing sarcoma family of tumors. Analysis for the translocation by routine cytogenetics or polymerase chain reaction analysis for the chimeric fusion gene products EWS/FLI1 or EWS/ERG can be helpful in confirming the diagnosis in very undifferentiated tumors.

Clinical Manifestations.

Symptoms of Ewing sarcoma are similar to those of osteosarcoma. Pain, swelling, limitation of motion, and tenderness over the involved bone or soft tissue are common presenting symptoms. In the case of huge chest wall primary tumors, patients may present with respiratory distress. Patients with paraspinal or vertebral primary tumors may present with symptoms of cord compression. Ewing sarcoma is often associated with systemic manifestations such as fever or weight loss; patients may have undergone treatment for a presumptive diagnosis of osteomyelitis. Patients may also have a delay in diagnosis when their pain or swelling is attributed to a sports injury.

Diagnosis.

The diagnosis of Ewing sarcoma should be suspected in a patient who presents with pain and swelling, with or without systemic symptoms, and with a radiographic appearance of a primarily lytic bone lesion with periosteal reaction, the characteristic **onion-skinning** (Fig. 493–3). A large associated soft tissue mass is often visualized on MRI or CT (Fig. 493–4). The differential diagnosis includes osteosarcoma, osteomyelitis, Langerhans cell histiocytosis, primary lymphoma of bone, metastatic neuroblastoma, or rhabdomyosarcoma in the case of a pure soft tissue lesion. Patients should be referred to a center with experience in managing bone tumors for evaluation and biopsy. Thorough evaluation for metastatic disease includes CT of the chest, radionuclide bone scan, and bone marrow aspirate and biopsy specimens from at least two sites. MRI of the tumor and the entire length of involved bone should be performed to determine the exact extension of the soft tissue and bony mass and the proximity of tumor to neurovascular structures. Biopsy should be performed preferably by the surgeon who will perform the ultimate surgical procedure to avoid compromising an ultimate potential for limb salvage by a poorly planned biopsy incision. CT-guided biopsy of the lesion often provides diagnostic tissue. It is important to obtain adequate tissue for special stains, cytogenetics, and molecular studies.

Treatment.

Ewing sarcoma family of tumors are best managed with a comprehensive multidisciplinary approach incorporating the surgeon, chemotherapist, and radiation oncologist in planning therapy. Multiagent chemotherapy is important because it can rapidly shrink the tumor and is generally given before attempting local control. The addition of ifosfamide and etoposide to the standard agents of vincristine, doxorubicin, and cyclophosphamide improves the outcome of nonmetastatic Ewing sarcoma. Chemotherapy usually causes dramatic shrinkage of the soft tissue mass and rapid significant pain relief. Recent randomized studies of chemotherapy in Ewing sarcoma are evaluating the role of dose intensity in treatment. Ewing sarcoma is considered a radiosensitive tumor, and local control may be achieved with radiation or surgery. Radiation therapy is associated with a risk of radiation-induced second malignancies, especially osteosarcoma, as well as failure of bone growth in skeletally immature patients. Many centers prefer surgical resection if possible to achieve local control. It is important to

Figure 493.1-3 Radiograph of tibial Ewing sarcoma showing periosteal elevation or “onion-skinning.”

provide patients with crutches if the tumor is in a weight-bearing bone to avoid a pathologic fracture before definitive local control. Chemotherapy should be resumed as soon as possible after surgery.

Prognosis.

Patients with small, nonmetastatic, distally located extremity tumors have the best

prognosis. Such patients enjoy up to a 75% cure rate. The type of chromosomal translocation may be related to prognosis. Patients with pelvic tumors have, until recently, had a much worse outcome. Patients with metastatic disease at diagnosis, especially bone or bone marrow metastases, have a poor prognosis, with fewer than 30% surviving long term. New approaches, such as very intensive chemotherapy with peripheral blood stem cell rescue, are being investigated in these patients.

Long-term follow-up of patients with Ewing sarcoma is important because of the potential for late effects of treatment such as anthracycline cardiotoxicity, second malignancies, especially in the radiation field, and late relapses even 10 yr after initial diagnosis.

493.2 Benign Tumors and Tumor-like Processes of Bone

Benign bone lesions in children are common in comparison with the relatively rare malignant neoplasms of bone and present diagnostic challenges (see Table 493–1). Some, although histologically benign, can be life threatening. No single history element or diagnostic test is sufficient to rule out malignancies or suggest non-neoplastic conditions. A broad range of diagnostic possibilities must be considered when confronted with an unknown bone lesion. Benign lesions may be painless or painful, especially if a pathologic fracture is impending. Night pain that awakens a child is suggestive of malignancy; relief of such pain with aspirin is common with benign lesions such as

Figure 493.2-4 Magnetic resonance image (MRI) of tibial Ewing sarcoma showing a large associated soft tissue mass.

osteoid osteomas. Rapidly enlarging lesions are usually associated with malignancy, but several benign lesions, such as aneurysmal bone cysts, may enlarge faster than most malignancies. Several conditions, such as osteomyelitis, may simulate the appearance of benign bone tumors.

Many benign bone tumors are diagnosed incidentally or after pathologic fracture. Management of these fractures is similar to that of nonpathologic fractures in the same location. It is unusual for benign bone tumors to interfere with fracture healing. Likewise, the fractures rarely result in changes or healing of these tumors, which are usually treated after the fracture has healed.

Radiographs of any suspected bone lesion should always be obtained in two planes. Additional studies may be necessary to help arrive at the correct diagnosis and to guide treatment. Despite the benign nature of these lesions, many require intervention.

Osteochondroma (exostosis) is one of the most common benign bone tumors in children. Many are completely asymptomatic and unrecognized. The true incidence of this lesion is therefore unknown. Most osteochondromas develop in childhood, arising from the metaphysis of long bones, particularly the distal femur, proximal humerus, and proximal tibia. The lesion enlarges with the child until skeletal maturity. Most are discovered from 5–15 yr of age when the child or parent notices a bony, nonpainful mass. Some are discovered when irritated by pressure during athletic or other activities. Osteochondromas appear radiographically as stalks or broad-based projections from the surface of the bone, usually in a direction away from the adjacent joint. Invariably, the lesion is radiographically smaller than suggested by palpation because the cartilage “cap” covering the lesion is not seen. This cartilage

cap may be up to 1?cm thick. Both the cortex of the bone and the marrow space of

the involved bone are continuous with the lesion. Malignant degeneration to a chondrosarcoma is rare in children but may occur in as many as 1% of adults. Routine removal is not performed unless the lesion is large enough to cause symptoms or if rapid growth occurs. **Multiple hereditary exostoses** is a related but rare condition characterized by the presence of multiple osteochondromas. Severely involved children may have short stature, limb-length inequality, premature partial physeal arrests, and deformity of both the upper and lower extremities. These individuals need to be monitored carefully during growth.

Enchondroma is a benign lesion of hyaline cartilage occurring centrally in the bone. The majority are asymptomatic and occur in the hands. Most are discovered incidentally, although pathologic fractures often lead to the diagnosis. Radiographically, the lesions occupy the medullary canal, are radiolucent, and are sharply marginated. Punctate or stippled calcification may be present within the lesion, but this is much more common in adults than children. The vast majority of enchondromas are solitary. Most can be observed, with curettage and bone grafting reserved for those lesions that are symptomatic or large enough to weaken the bone structurally. Multifocal involvement is referred to as **Ollier disease** and may result in bony dysplasia, short stature, limb-length inequality, and joint deformity. Surgery may be necessary to correct or prevent such deformities. When multiple enchondromas are associated with angiomas of the soft tissue, the condition is referred to as **Maffucci syndrome**. A high rate of malignant transformation has been reported in both of these multifocal conditions.

Chondroblastoma is a rare lesion usually found in the epiphysis of long bones. Most patients present in the 2nd decade with complaints of mild to moderate pain in the adjacent joint. Common sites include the hip, shoulder, and knee. Muscle atrophy and local tenderness may be the only clinical findings. The lesion appears radiographically as a sharply marginated radiolucency within the epiphysis or apophysis, occasionally with metaphyseal extension across the physis. Proximity to the joint may cause deformity of the subchondral bone, an effusion, or erosion into the joint. Recognition is important because most lesions can be cured with curettage and bone grafting before joint destruction occurs.

Chondromyxoid fibroma is an uncommon benign bone tumor in children. This metaphyseal lesion usually causes pain and local tenderness. The lesion may occasionally be asymptomatic. Chondromyxoid fibroma appears radiographically as an eccentric, lobular, metaphyseal radiolucency with sharp, sclerotic, and scalloped margins. The lower extremity is most often involved. Treatment usually consists of curettage and bone grafting or en bloc resection.

Osteoid osteoma is a small benign bone tumor; most of these tumors are diagnosed between 5–20 yr of age. The clinical pattern is characteristic, consisting of unremitting and gradually increasing pain that is often worst at night and relieved by aspirin. Males are affected more often than females. Any bone can be involved, but the most common sites are the proximal femur and tibia. Vertebral lesions may cause scoliosis or symptoms that mimic a neurologic disorder. Examination may reveal a limp, atrophy, and weakness when the lower extremity is involved. Palpation and range of motion do not alter the discomfort. Radiographs are distinctive, showing a round or oval metaphyseal or diaphyseal lucency (0.5–1.0?cm diameter) surrounded by sclerotic bone. The central lucency, or nidus, shows intense uptake on bone scan. About 25% of osteoid osteomas are not visualized on plain radiographs but can be identified with CT. Because of the small size of the lesion and the location adjacent to thick cortical bone, MRI is poor at detecting osteoid osteomas. Treatment is directed at removing the lesion. This may involve en bloc excision, curettage, or percutaneous CT-guided ablation of the nidus. Patients with mild pain may be treated with salicylates. Some lesions spontaneously resolve after skeletal maturity.

Osteoblastoma is a locally destructive, progressively growing lesion of bone with a predilection for the vertebrae, although almost any bone may be involved. Most patients note the insidious onset of dull aching pain, which may be present for months before they seek medical attention. Spinal lesions may cause neurologic symptoms or deficits. The radiographic appearance is variable and less distinctive than that of other benign bone tumors. About 25% show features suggesting a malignant neoplasm, making biopsy necessary in many cases. Expansile spinal lesions often involve the posterior elements. Treatment involves curettage and bone grafting or en bloc excision, taking care to preserve nerve roots when treating spinal lesions. Surgical stabilization of the spine may be necessary.

Fibromas (nonossifying fibroma, fibrous cortical defect, metaphyseal fibrous defect) are fibrous lesions of bone that occur in 40% of children older than 2 yr of age. They likely represent a defect in ossification rather than a neoplasm. As such, these lesions are usually asymptomatic. Most are discovered incidentally when radiographs are taken for other reasons, usually to rule out a fracture after trauma. Occasional pathologic fractures can occur through rare large lesions. Physical examination is usually unrevealing. Radiographs show a sharply marginated eccentric lucency in the metaphyseal cortex. Lesions may be multilocular and expansile, with extension from the cortex into the medullary bone. The long axis of the lesion is parallel with that of the bone. Approximately 50% are bilateral or multiple. Because of the characteristic radiographic appearance, most lesions do not require biopsy or treatment. Spontaneous regression can be expected after skeletal maturity. Curettage and bone grafting may be recommended for lesions occupying more than 50% of the bone diameter because of the risk of a pathologic fracture.

Unicameral bone cysts can occur at any age in childhood but are rare before 3 yr of age and after skeletal maturity. The cause of these fluid-filled lesions is unknown. Some resolve spontaneously after skeletal maturity. Most are asymptomatic until diagnosis, which usually follows a pathologic fracture. Such fractures may occur with relatively minor trauma, such as with throwing or catching a ball. Unicameral bone cysts appear radiographically as solitary, centrally located lesions within the medullary portion of the bone. These cysts are most common in the proximal humerus or femur. They often extend to (but not through) the physis and are sharply marginated. Thinning and expansion of the cortex occurs but does not exceed the width of the adjacent physis. Treatment involves allowing the pathologic fracture to heal, followed by aspiration and injection with methylprednisolone or bone marrow. Repeat injections, curettage, and bone grafting are occasionally necessary to treat

recurrent lesions.

Aneurysmal bone cyst is a reactive lesion of bone seen during the 1st and 2nd decades of life. The lesion is characterized by cavernous spaces filled with blood and solid aggregates of tissue. Although the femur, tibia, and spine are most commonly involved, this progressively growing, expansile lesion develops in any bone. Pain and swelling are common. Spinal involvement may lead to cord or nerve root compression and associated neurologic symptoms, including paralysis. Radiographs show eccentric lytic destruction and expansion of the metaphysis surrounded by a thin sclerotic rim of bone. Posterior elements of the spine are more commonly involved than the vertebral body. Unlike most other benign bone tumors, which are usually confined to a single bone, aneurysmal bone cysts may involve adjacent vertebrae. Rapid growth is characteristic and may lead to confusion with malignant neoplasms. Treatment consists of curettage and bone grafting or excision. Spinal lesions may require stabilization after excision. As with other benign tumors, attempts are made to preserve nerve roots and other

vital structures. Recurrence after surgical treatment occurs in 20–30%, is more common in younger than older children, and usually occurs in the first 1–2 yr after treatment.

Fibrous dysplasia is a developmental abnormality characterized by fibrous replacement of cancellous bone. Lesions may be solitary or multifocal (polyostotic), relatively stable, or progressively more severe. Most children are asymptomatic, although those with skull involvement may have swelling or exophthalmos. Pain and limp are characteristic of proximal femoral involvement. Limb-length discrepancy, bowing of the tibia or femur, and pathologic fractures may be presenting complaints. The triad of polyostotic disease, precocious puberty, and cutaneous pigmentation is known as **Albright syndrome.** Radiographic features of fibrous dysplasia include a lytic or ground-glass expansile lesion of the metaphysis or diaphysis. The lesion is sharply marginated and often surrounded by a thick rim of sclerotic bone. Bowing, especially of the proximal femur, may be present. Treatment usually involves observation. Surgery is indicated for patients with progressive deformity, pain, or impending pathologic fractures. Bone grafting is not as successful in the treatment of fibrous dysplasia as with other benign tumors because the lesion often recurs within the grafted bone. Reconstructive surgical techniques are often necessary to provide stability.

Osteofibrous dysplasia is a lesion that affects children 1–10 yr old. This lesion usually involves the tibia. It is clinically, radiographically, and histologically distinct from fibrous dysplasia. Most children present with anterior swelling or enlargement of the leg, and most have no pain unless there is an associated pathologic fracture. Progression is unlikely after 10 yr of age. Radiographs show solitary or multiple lucent, cortical, diaphyseal lesions surrounded by sclerosis. Anterior bowing of the tibia is often present. The radiographic appearance closely resembles that of adamantinoma, a malignant neoplasm, making biopsy more common than with other benign bone tumors. Treatment involves observation. Some lesions heal spontaneously. Excision and bone grafting should be delayed after age 10 yr because of a high recurrence rate after this age. Pathologic fractures heal with immobilization.

Eosinophilic granuloma is a monostotic or polyostotic disease with no extraskeletal involvement. This latter finding distinguishes eosinophilic granuloma from the other forms of Langerhans cell histiocytosis (Hand-Schüller-Christian or Letterer-Siwe variants), which may have a less favorable prognosis (see Chapter 499). Eosinophilic granuloma usually occurs during the first 3 decades of life and is most common in boys 5–10 yr of age. The skull is most commonly affected, but any bone may be involved. Patients usually present with local pain and swelling. There is often marked tenderness and warmth in the area of the involved bone. Spinal lesions may cause pain, stiffness, and occasional neurologic symptoms. The radiographic appearance of the skeletal lesions is similar in all forms of Langerhans cell histiocytosis but is variable enough to mimic many other benign and malignant lesions of bone. The radiolucent lesions have well-defined or irregular margins with expansion of the involved bone and periosteal new bone formation. Spine involvement may cause uniform compression or flattening of the vertebral body. A skeletal survey is warranted because polyostotic involvement and the typical skull lesions strongly suggest the diagnosis of eosinophilic granuloma. Biopsy is often necessary to confirm the diagnosis because of the broad radiographic differential diagnosis. Treatment includes curettage and bone grafting, low-dose radiation therapy, or steroid injection. Observation for symptomatic lesions is reasonable because most osseous lesions heal spontaneously and do not recur. Children with bone lesions should be evaluated for visceral involvement because treatment of Hand-Schüller-Christian disease and Letterer-Siwe disease is more complex and often systemic.

Chapter 494 - Retinoblastoma

Cynthia E. Herzog

Epidemiology.

Retinoblastoma occurs at a rate of 3.7 cases/million in the United States, with no racial or gender predilection. Overall, about 60% of cases are unilateral and nonhereditary, 15% unilateral and hereditary, and 25% bilateral and hereditary. Bilateral involvement is found in 42% of those presenting when younger than 1 yr of age but in only 21% of those presenting during 1 yr of age and is even less common at older ages of presentation.

The hereditary form is associated with a germline defect in the retinoblastoma gene *(RB1)* located on the long arm of chromosome 13. *RB1* encodes a tumor suppressor protein. Familial cases are generally multifocal and bilateral, whereas nonfamilial cases tend to have unilateral, unifocal involvement. According to the “two-hit” model, two mutational events are required for tumor development. In the heritable form, one mutated *RB* gene is inherited through the germ line and a second mutation occurs subsequently in the somatic retinal cell. In the noninherited form, both mutations occur in retinal cells.

Pathogenesis.

The histology of retinoblastoma is a small, round, blue cell tumor with rosette formation. It may arise in any of the nucleated layers of the retina and exhibits various degrees of differentiation; it tends to outgrow its blood supply, resulting in necrosis and calcification.

Endophytic tumors arise from the inner surface of the retina, grow into the vitreous, and tend to seed to other areas of the retina. **Exophytic tumors** grow from the outer retinal layer and may produce retinal detachment. Hematogenous or lymphatic spread to more distant sites can occur with extension to the choroid or along the optic nerve beyond the lamina cribrosa.

Clinical Manifestations.

Only about 10% of retinoblastomas are detected by routine ophthalmologic

screening in the context of a positive family history. Retinoblastoma classically presents with **leukocoria,** a white pupillary reflex (Fig. 494–1). This abnormality is often first noticed when a red reflex is not present at routine newborn or well-child examination or in a flash photograph of the child. Strabismus is commonly the initial presenting complaint. Orbital inflammation, hyphema, or pupil irregularity occurs with advancing disease. Pain is usually a feature if secondary glaucoma is present.

Diagnosis.

The diagnosis does not require a biopsy but is established by characteristic ophthalmologic findings. Evaluation generally requires an examination under general anesthesia by

Figure 494-1 *A*, Leukocoria noted in the left eye of a child presenting with retinoblastoma. *B*, A large white tumor mass noted within the posterior chamber of the enucleated eye. (From Shields JA, Shields CL: Current management of retinoblastoma. *Mayo Clin Proc* 1994;69:50–6.)

an ophthalmologist to obtain a complete visualization of both eyes, which also facilitates photographing and mapping of the tumors. Retinal detachment or vitreous hemorrhage can complicate the evaluation.

Orbital ultrasonography and CT or MRI are used to evaluate the extent of intraocular disease and extraocular spread. Occasionally, a pineal area tumor will be detected, a phenomenon known as **trilateral retinoblastoma.** MRI allows for better evaluation of optic nerve involvement. Bone scan, cerebrospinal fluid evaluation, and bone marrow evaluation are necessary only if indicated by other clinical, laboratory, or imaging studies.

The differential diagnosis includes hyperplastic primary vitreous, Coats disease, cataract, visceral larva migrans, choroidal coloboma, and retinopathy of prematurity.

Treatment.

The treatment is determined by the size and location of the tumor, with the primary goal being cure and a secondary goal of preserving vision. As newer modalities for local control of intraocular tumor and more effective systemic chemotherapy have been developed, primary enucleation is less frequently undertaken routinely.

Most unilateral disease presents as a large tumor. Enucleation is undertaken if there is no potential for useful vision. In bilateral disease the traditional approach involves enucleation of the more severely affected eye and irradiation of the remaining eye in hope of salvaging some useful vision. With the availability of effective chemotherapy, an attempt can be made to salvage both eyes with some degree of functional vision. If feasible, small tumors can be treated with laser photocoagulation or cryotherapy with careful follow-up for evidence of recurrence or new tumor growth. Larger tumors often respond to multiagent chemotherapy, including carboplatin, vincristine, and etoposide, thus facilitating successful focal therapy. If this approach fails, external-beam irradiation or brachytherapy should be considered, although this approach may result in significant orbital deformity and increased incidence of second malignancies in patients with germ line mutations. Enucleation may be required for nonresponsive or recurrent tumors.

Prognosis.

Close to 95% of retinoblastomas are cured in the United States, where extraocular extension is rarely seen. Current efforts using chemotherapy in combination with local therapy are focused on trying to preserve useful vision and avoidance of irradiation or enucleation. Routine ophthalmologic examinations should continue until about 6 yr of age to detect new lesions. The prognosis for patients with metastases is poor.

Children with germ line *RB1* mutations are at significant risk for development of second malignancies, primarily osteosarcoma. This risk is further increased by the use of radiation therapy. Other radiation-related complications include cataracts, orbital growth deformities, lacrimal dysfunction, and late retinal vascular injury.

Chapter 495 - Gonadal and Germ Cell Neoplasms

Cynthia E. Herzog

Epidemiology.

Malignant germ cell tumors (GCTs) and gonadal tumors occur with an incidence of 12 cases/million in persons younger than 20 yr of age. Most malignant tumors of the gonads in children are GCTs. The incidence varies according to age and sex of the patient. Sacrococcygeal tumors occur predominantly in female infants. Testicular GCTs occur predominantly before age 4 yr and after puberty. Testicular GCTs occur with much greater frequency in whites than in blacks, whereas ovarian tumors have a slight predominance in blacks. Undescended testes are associated with an increased risk of testicular cancer.

Pathogenesis.

The GCTs and non-GCTs arise from primordial germ cells and coelomic epithelium, respectively. GCTs may contain benign and malignant elements in different areas of the tumor; extensive sectioning is essential to make the correct diagnosis. There are many histologically distinct subtypes of GCTs, including teratomas (mature and immature), endodermal sinus tumor, and embryonal carcinoma (Fig. 495–1). Non-GCTs of the ovary include epithelial (serous and mucinous) and sex cord/stromal tumors; testicular tumors include sex cord/stromal tumors (e.g., Leydig cell, Sertoli cell).

Clinical Manifestations and Diagnosis.

The clinical presentation of germ cell neoplasms depends on location. Ovarian tumors are often quite large before diagnosis. Extragonadal GCTs occur in the midline, including the suprasellar region, pineal region, neck, mediastinum, and retroperitoneal and sacrococcygeal areas. Symptoms relate to mass effect, but the intracranial GCTs often present with anterior and posterior pituitary deficits.

a-Fetoprotein (AFP) level is elevated in endodermal sinus tumors and may have minimally elevated levels in teratomas. Infants have elevated levels of AFP that reach adult normal by about 8 mo; therefore, high AFP levels must be interpreted with

Figure 495-1 Tumors of germ cell origin. (Adapted from Pierce GB, Abell MR: Embryonal carcinoma of the testis. *Pathol Annu* 1970;5:27–60.)

caution in this age group. Elevation of the ß subunit of human chorionic gonadotropin (ß-hCG) is seen in choriocarcinoma and germinomas. Lactate dehydrogenase (LDH), although nonspecific, is sometimes a useful marker. If elevated, these markers provide important confirmation of the diagnosis and serve as a means to monitor the patient for tumor response and recurrence. Both serum and cerebrospinal fluid should be assayed for these markers in the case of intracranial lesions.

Diagnosis begins with physical examination and imaging studies, including plain radiographs of the chest and ultrasonography of the abdomen. CT or MRI can further delineate the primary tumor. If germ cell malignancy is strongly suggested, preoperative staging with CT of the chest and bone scan is appropriate. Primary surgical resection is indicated for tumors deemed resectable. The exception is intracranial lesions; in this site, the diagnosis can be made with imaging and AFP or ß-hCG determinations. For intracranial lesions, primary therapy comprises irradiation and chemotherapy.

Gonadoblastoma frequently occurs in patients with gonadal dysgenesis and a Y chromosome. This syndrome is characterized by failure to fully masculinize the external genitalia. If this syndrome is diagnosed, imaging with ultrasonography or CT of the gonad is performed, and surgical resection of the tumor is generally curative. Prophylactic resection of dysgenetic gonads at the time of diagnosis is recommended because gonadoblastomas, some of which contain malignant germ cell tumor elements, frequently develop. Gonadoblastomas may produce abnormal amounts of estrogen.

Teratomas occur in many locations, presenting as masses. They are not associated with elevated markers unless malignancy is present. The sacrococcygeal region is the most frequent tumor site of teratomas. Sacrococcygeal teratomas occur most commonly in infants and may be diagnosed in utero, or at birth, with the majority arising in females. The frequency of malignancy in this location varies from less than 10% when younger than 2 mo of age to more than 50% when older than 4 mo of age.

Germinomas occur intracranially, in the mediastinum, and in the gonads. In the ovary, they are called **dysgerminomas;** in the testis, **seminomas**. They are usually tumor marker negative despite being malignant. **Endodermal sinus or yolk sac tumor** and **choriocarcinoma** appear highly malignant by histologic criteria. Both occur at gonadal and extragonadal sites. **Embryonal carcinoma** most often occurs in the testes.

Non–germ cell gonadal tumors are very uncommon in pediatrics and occur

predominantly in the ovary. **Epithelial carcinomas** (usually an adult tumor), **Sertoli-Leydig cell tumors**, and **granulosa cell tumors** may occur in children. Both of the latter tumors produce hormones that can cause virilization or feminization or precocious puberty, depending on pubertal stage and the balance between Sertoli (estrogen production) and Leydig cells (androgen production). Diagnostic evaluation usually focuses on the chief complaint of inappropriate sex steroid effect and includes hormone measurements, which reflect gonadotropin-independent sex steroid production. Appropriate imaging, to rule out a functioning gonadal tumor, is also performed. Surgery is usually curative. Effective therapy for nonresectable disease has not been found.

Treatment.

Complete surgical excision of the tumor is generally indicated, except for patients with central nervous system (CNS) primary tumors. For testicular tumors, an inguinal approach is indicated. When complete excision cannot be accomplished, preoperative chemotherapy is indicated, with second-look surgery. For teratomas, both mature and immature, and completely resected malignant tumors, surgery alone is the treatment. Cisplatin-based chemotherapy regimens are generally curative in GCTs that cannot be completely resected, even if metastases are present. Except for GCTs of the CNS, irradiation is limited to those tumors that are not amenable to complete excision and are refractory to chemotherapy.

Prognosis.

The overall cure rate for children with GCTs is more than 80%. There is little impact of histology or site on prognosis, although nonresected extragonadal GCTs have a slightly worse prognosis.

Chapter 496 - Neoplasms of the Liver

Cynthia E. Herzog

Hepatic tumors are rare in children. Primary tumors of the liver account for approximately 1% of malignancies in children, with an annual incidence of 1.6 cases/million children in the United States. From 50–60% of hepatic tumors in children are malignant, with more than 65% of these malignancies being hepatoblastomas and most of the remainder hepatocellular carcinomas. Rare hepatic malignancies include angiosarcoma, malignant germ cell tumor, rhabdomyosarcoma of the liver, and undifferentiated sarcoma. More common childhood malignancies such as neuroblastoma and lymphoma can metastasize to the liver. Benign liver tumors, which usually present within the first 6 mo of life, include hemangiomas, hamartomas, and hemangioendotheliomas.

HEPATOBLASTOMA

Epidemiology.

Hepatoblastoma occurs predominantly in children younger than 3 yr of age. The etiology is unknown. Hepato- blastomas are associated with familial adenomatous polyposis; alterations in the antigen-presenting cell (APC)/ß-catenin pathway have been found in a majority of tumors evaluated. Hepatoblastoma is also associated with Beckwith-Wiedemann syndrome, which can show a similar loss of genomic imprinting of the insulin-like growth factor-2 gene. Low birthweight is associated with increased incidence of hepatoblastoma, with the risk increasing as birthweight decreases.

Pathogenesis.

Hepatoblastoma can be epithelial type, containing fetal or embryonal malignant cells (either as a mixture or as pure elements), or the mixed type, containing mesenchymal and epithelial elements. Pure fetal histology predicts a more favorable outcome.

Clinical Manifestations.

Hepatoblastoma generally presents as a large, asymptomatic abdominal mass. It arises from the right lobe three times more often than the left and is usually unifocal. As the disease progresses, weight loss, anorexia, vomiting, and abdominal pain may ensue. Metastatic spread of hepatoblastoma most commonly involves regional lymph nodes and the lungs.

A valuable serum tumor marker, a-fetoprotein (AFP), is used in the diagnosis and monitoring of hepatic tumors. AFP level is elevated in almost all hepatoblastomas. Bilirubin and liver enzymes are usually normal. Anemia is common, and thrombocytosis occurs in about a third of patients. Hepatitis B and C serology should be obtained but are usually negative in hepatoblastoma.

Diagnostic imaging should include plain radiographs and ultrasonography of the abdomen to characterize the hepatic mass. Ultrasonography can differentiate malignant hepatic masses from benign vascular lesions. Either CT or MRI is an accurate method of defining the extent of intrahepatic tumor involvement and the potential for surgical resection. Evaluation for metastatic disease should include CT of the chest and bone scan.

Treatment.

In general, the cure of malignant hepatic tumors in children depends on complete resection of the primary tumor. As much as 85% of the liver can be resected, with hepatic regeneration noted within 3–4 mo after surgery. Cisplatin in combination with vincristine and 5-fluorouracil or doxorubicin is effective treatment for hepatoblastoma and increases the chances of cure after complete surgical resection. In low-stage tumors, survival rates more than 90% can be achieved with multimodal treatment, including surgery and adjuvant chemotherapy. With tumors unresectable at diagnosis, survival rates of approximately 60% can be obtained. Metastatic disease further reduces survival, but complete regression of disease can often be obtained with chemotherapy and surgical resection of the primary tumor and isolated pulmonary metastatic disease, resulting in survival rates of about 25%.

HEPATOCELLULAR CARCINOMA

Epidemiology.

Hepatocellular carcinoma occurs mostly in adolescents and is often associated with hepatitis B or C infection. It is more common in East Asia and other areas where hepatitis B is endemic. In these areas it also tends to occur in a bimodal pattern, with the younger age peak overlapping the age of hepatoblastoma presentation. It also occurs in the chronic form of hereditary tyrosinemia, glycogen storage disease, a_1 -antitrypsin deficiency, and biliary cirrhosis.

Pathogenesis.

Hepatocellular carcinoma generally presents as a multicentric, invasive tumor consisting of large pleomorphic cells with a lack of underlying cirrhosis. The fibrolamellar variant of hepatocellular carcinoma has a somewhat better prognosis.

Clinical Manifestations.

Hepatocellular carcinoma generally presents as a hepatic mass, abdominal distention, and symptoms of anorexia, weight loss, and abdominal pain. Hepatocellular carcinoma can present as an acute abdominal crisis with rupture of the tumor and hemoperitoneum. AFP level is elevated in approximately 60% of children with hepatocellular carcinoma. Evidence of hepatitis B and C infection is usually found in areas where it is endemic, but not in Western countries or with the fibrolamellar type. Bilirubin is usually normal, but liver enzymes may be abnormal.

Diagnostic imaging should include plain radiographs and ultrasonography of the abdomen to characterize the hepatic mass. Ultrasonography can differentiate malignant hepatic masses from benign vascular lesions. Either CT or MRI is an accurate method of defining the extent of intrahepatic tumor involvement and the potential for surgical resection. Evaluation for metastatic disease should include CT of the chest and bone scan.

Treatment.

Because of the multicentric origin of hepatocellular carcinoma, complete resection of this tumor is accomplished in only 30–40% of cases. Even with complete surgical resection, only 30% of children are long-term survivors. Chemotherapy, including cisplatin, doxorubicin, etoposide, and 5-fluorouracil, has shown some activity against this tumor, but improved long-term outcome has been difficult to achieve. Other techniques such as chemoembolization and liver transplantation are under study as therapy for hepatocellular carcinomas.

Chapter 497 - Benign Vascular Tumors

Cynthia E. Herzog

HEMANGIOMAS

Hemangiomas are the most common benign tumors of infancy and occur in about 10% of term infants. The risk of hemangioma is 3 times higher in females than males. The risk is doubled in premature infants and 10 times higher in offspring of women who had chorionic villus sampling. Although hemangiomas can be present at birth, they usually arise shortly after birth and grow rapidly during the first year of life, with slowing of growth in the next 5 yr and involution by 10–15 yr of age.

Clinical Manifestations.

More than half of these tumors are located in the head and neck region. The majority are solitary lesions, but the presence of more than one cutaneous lesion increases the likelihood of visceral hemangiomas. The liver is the primary site of visceral involvement; other involved organs include the brain, intestines, and lung. Most hemangiomas require no therapy, but approximately 10% of hemangiomas cause significant impairment and 1% are life threatening because of their location. Hemangiomas around the airway can cause airway obstruction, and those around the eyes can result in loss of vision. Ulceration is a frequent complication and can lead to secondary infection. Large hepatic hemangiomas or hemangioendotheliomas may result in hepatomegaly, anemia, thrombocytopenia, and high-output heart failure.

Kasabach-Merritt syndrome is characterized by rapidly enlarging lesion, thrombocytopenia, microangiopathic hemolytic anemia, and coagulopathy as a result of platelet and red blood cell trapping and activation of the clotting system within the vasculature of the hemangioma. This syndrome has now been shown to be associated with kaposiform hemangioendotheliomas or tufted hemangiomas.

Cutaneous lesions can usually be diagnosed by typical appearance and rapid proliferation. Deep lesions may require imaging studies to help differentiate from a lymphangioma. The presence of a midline hemangioma in the lumbosacral area

indicates the need for an MRI for underlying asymptomatic neurologic abnormalities. Location may also dictate the need for an ophthalmologic or surgical consultation. A scan of the liver should be performed if multiple cutaneous lesions are present.

Treatment.

Most require no specific therapy and only parental reassurance. For those hemangiomas that are life threatening or that threaten vital functions such as eyesight, treatment is warranted. Prednisone (1–3?mg/kg/24?hr PO) is typically the initial therapy. Occasionally, higher doses are used. Approximately 30% of hemangiomas respond dramatically to corticosteroids and begin to regress within 1 wk; 40% stabilize or show minimal response; and the remainder do not respond. Interferon-a (1–3?MU/m^2 /24?hr) has also been used as initial therapy and in those that do not respond to corticosteroid therapy. Although response rates of up to 70% have been reported, the risk of neurologic adverse effects in 10–20% indicates the need for caution in using interferon-a. Laser therapy has been used in some situations.

Treatment of patients with Kasabach-Merritt syndrome usually consists of supportive care while also beginning therapy with corticosteroids or interferon-a. Heparin therapy is contraindicated, and platelet transfusions should be avoided in the absence of life-threatening hemorrhage because they may exacerbate the bleeding. The use of aminocaproic acid or tranexamic acid may be beneficial. Failure to respond to therapy warrants the use of less conventional treatments, such as irradiation, embolization, or surgical resection.

LYMPHANGIOMAS AND CYSTIC HYGROMAS

Lymphatic malformations, including lymphangiomas and cystic hygromas, which arise in the embryonic lymph sac, are the second most common benign vascular tumors in children. About half are located in the head and neck area. Approximately 50% are present at birth, with most presenting by 2 yr of age. There is no gender predisposition. Spontaneous regression has been reported but is not typical.

Lymphatic malformations present as soft, painless masses that transilluminate if superficial. Intrathoracic lymphatic malformation can present as symptoms related to a mediastinal mass or pericardial or pleural effusion. Rapid enlargement can occur with infection or hemorrhage. Localized lesions may be surgically resected, but this can be difficult, owing to their infiltrative nature. Recurrence is common with incompletely resected lesions. Aspiration can provide temporary relief in an emergency, such as in the presence of dyspnea, but reaccumulation will occur. Treatment by injection of sclerosing agents and laser therapy has also been used. Systemic therapy with interferon has also been reported.

Chapter 498 - Rare Tumors

Cynthia E. Herzog

THYROID TUMORS

The incidence of thyroid cancer in patients younger than 20 yr of age is 4.9 cases/million in the United States. Most thyroid cancer in this age group occurs in the adolescent female. Thyroid cancer occurrence is about 4 times greater in females than males and 2.5 times more common in whites than blacks. The greatest risk factor for thyroid cancer is radiation exposure, especially from head and neck irradiation. Thyroid cancer accounts for about 10% of second malignancies among cancer survivors, especially survivors of Hodgkin lymphoma. This is due to treatment not only with radiation but also with alkylating agents. The vast majority are differentiated carcinomas (papillary or follicular). However, medullary thyroid carcinoma (MTC) may occur in familial cases, especially with multiple endocrine neoplasia (MEN type 2). MEN type 2b is associated with onset of MTC at a very early age. Other findings of MEN 2b include mucosal neuromas and marfanoid habitus. MEN type 2 is associated with mutations in the *RET* proto-oncogene, whereas genetic translocations involving *RET* are found in about half of the pediatric thyroid cancers with differentiated histology.

Patients present with a thyroid mass and/or cervical lymphadenopathy; symptoms related to abnormal hormone levels are rare. About 20% of thyroid nodules in young children are malignant, compared with about 10% in adolescents and adults. Fine-needle aspiration (FNA) is commonly used to assess thyroid

nodules in adults, but the use of FNA in the pediatric population has not been firmly established, especially in preadolescent patients; surgical resection of nodules is recommended for these patients. Evaluation should include determination of thyroid hormone levels, thyroid scan, chest radiography, and CT of the chest. Total thyroidectomy for disease confined to one lobe remains controversial in pediatrics owing to good prognosis and the risk of complications such as hypoparathyroidism. With more extensive disease, or radiation-related cancer, total thyroidectomy is indicated, with lymph node dissection if cervical nodes are involved. Treatment with iodine-131 is then used to eradicate residual disease and treat pulmonary metastases, which occur in 6–10% of cases. Pulmonary metastases are best detected with radioiodine after resection of bulk disease. **REFERENCES**

Skinner MA: Cancer of the thyroid gland in infants and children. *Semin Pediatr Surg* 2001;10:119–26.

MELANOMA

The incidence of melanoma in persons younger than 20 yr of age is 4.2 cases/million in the United States, with almost all of these cases occurring in adolescents. Incident rates of melanoma in younger age groups have remained stable in the United States, but the incidence is rapidly increasing in adults. Although sun exposure is a well-known risk factor for melanoma in adults, its role in pediatric melanoma is less clear. Pediatricians should counsel patients regarding avoidance of sun exposure to decrease the risk of later development of melanoma. Patients with fair skin and a family history of melanoma are at particularly high risk. Known risk factors in pediatrics are giant hairy nevus (>20?cm), dysplastic nevus syndrome, and xeroderma pigmentosum.

Findings of a rapidly enlarging nevus that is dark or has changed colors, has irregular borders, or bleeds easily should raise a concern of melanoma. Diagnosis is based on pathology. However, extra care must be taken in the diagnosis of melanoma in children because the distinction from other lesions, particularly Spitz nevus, can be difficult.

Treatment recommendations are based on adult data. The primary treatment is local excision with lymph node mapping and biopsy for all but the most superficial melanomas. If the sentinel node is positive, a formal lymph node dissection is recommended. Chemotherapy in combination with biologic agents and vaccine therapy has been used for treatment of distant metastases. Whether the outcome is better for children than adults is unclear.

NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma is rare in the pediatric population, but is one of the most common nasopharyngeal tumors to occur in pediatric patients. In adults it occurs with highest incidence in South China, but it also has a high incidence among Eskimos and in North Africa and Northeast India. In China, it is rare in the pediatric population, but in other populations a substantial proportion of cases occur in the pediatric age group, primarily in adolescents. It occurs in males twice as often as in females. In the pediatric population the tumors are more commonly of undifferentiated histology and associated with Epstein-Barr virus.

Most pediatric patients present with advanced locoregional disease manifest by cervical lymphadenopathy. Epistaxis, trismus, and cranial nerve deficits may also be present. The diagnosis is established from biopsy of the nasopharynx or cervical lymph nodes. In most cases the lactate dehydrogenase level is elevated, but this finding is nonspecific. Evaluation of the head and neck with CT or MRI is performed to determine the extent of locoregional disease. Chest radiography, CT, bone scan, and liver scan are used to evaluate for metastatic disease.

Treatment is a combination of chemotherapy and irradiation. Cisplatin-based chemotherapy is given before or concurrent with irradiation. The outcome depends on the extent of disease; those with distant metastases have a very poor prognosis. Late effects as a result of radiation therapy are common, including hormonal dysfunction, dental caries, fibrosis, and second malignancies.

ADENOCARCINOMA OF THE COLON AND RECTUM

Colorectal carcinoma rarely presents in the pediatric population. There is a male predominance, as compared with a female predominance in adults. Even in patients with predisposing conditions, such as familial adenomatous polyposis and Peutz-Jeghers syndrome, cancer usually does not present until adulthood, although screening should begin during childhood or adolescence. Presenting symptoms include bloody stools or melena, abdominal pain, weight loss, and changes in bowel pattern. Signs are often vague, often resulting in a delay in diagnosis and advanced disease. The histologic subtype differs from that seen in adults, with the majority of pediatric tumors being mucinous. Treatment consists of surgical resection when possible, with chemotherapy for unresectable tumors. Irradiation is useful in the treatment of rectal carcinomas.

ADRENOCORTICAL CARCINOMA

Adrenocortical carcinoma is rare but is associated with the Li-Fraumeni and Beckwith-Wiedemann syndromes. It may occur at any age during childhood but is more common during the first few years of life. In Brazil, there is a 10-fold higher frequency of childhood adrenocortical carcinoma, with a female predominance. Patients typically present with endocrine symptoms of Cushing syndrome or virilization. Most tumors are secretory, producing androgens, glucocorticoids, or estrogens. Prognosis depends on tumor size, extent of tumor, and resectability. Although responses are seen to mitotane- and cisplatin-based chemotherapy, the prognosis is poor for unresectable or metastatic disease.

Chapter 499 - Histiocytosis Syndromes of Childhood

Stephan Ladisch

The childhood histiocytoses constitute a diverse group of disorders, which, although rare in occurrence, may be severe in their clinical expression. These disorders are grouped together because they have in common a prominent proliferation or accumulation of cells of the monocyte-macrophage system of bone marrow origin. Although these disorders are sometimes difficult to distinguish clinically, accurate diagnosis is nevertheless essential for facilitating progress in treatment. To this end, a systematic classification of the childhood histiocytoses has been developed (Table 499–1). This diagnostic classification rests on

TABLE 499-1 -- **Classification of the Childhood Histiocytoses**

	Diseases	Cellular Characteristics of the Lesions	Treatment
Class I	Langerhans cell histiocytosis	Langerhans cells (CD1a positive) with Birbeck granules	Local therapy for isolated lesions; chemotherapy for disseminated disease
Class II	Familial erythrophagocytic lymphohistiocytosis	Morphologically normal reactive macrophages with prominent erythrophagocytosis	Chemotherapy; allogeneic bone marrow transplantation
	Infection-associated hemophagocytic syndrome		
Class III	Malignant histiocytosis	Neoplastic proliferation of cells with characteristics of monocytes/macrophages or their precursors	Antineoplastic chemotherapy, including anthracyclines

	Acute monocytic leukemia		

histopathologic findings; thus, a thorough, comprehensive evaluation of a biopsy specimen obtained at the time of diagnosis is essential. This evaluation includes studies (electron microscopy, immunostaining) that may require special sample processing.

Classification and Pathology.

Three classes of childhood histiocytosis are recognized, based on histopathologic findings. The most well-known childhood histiocytosis, previously known as **histiocytosis X,** constitutes class I and includes the clinical entities of eosinophilic granuloma (see Chapter 493), **Hand-Schüller-Christian disease,** and **Letterer-Siwe disease.** The name **Langerhan cell histiocytosis** (LCH) has been applied to the class I histiocytoses. The normal Langerhans cell is an antigen-presenting cell (APC) of the skin. The hallmark of LCH in all forms is the presence of a clonal proliferation of cells of the monocyte lineage containing the characteristic electron microscopic findings of a Langerhans cell. This is the **Birbeck granule,** a tennis racket–shaped bilamellar granule, which when seen in the cytoplasm of lesional cells in LCH is diagnostic of the disease. Alternatively, the definitive diagnosis of LCH can be made by demonstrating CD1a positivity of lesional cells. The lesions may contain various proportions of these Langerhans granule–containing cells, lymphocytes, granulocytes, monocytes, and eosinophils.

In contrast to a prominence of an APC (the Langerhans cell) in the class I histiocytoses, the class II histiocytoses are characterized by accumulation of antigen-processing cells (i.e., macrophages). With the characteristic morphology of normal macrophages by light microscopy, these phagocytic cells lack the two markers (Birbeck granules and CD1a positivity) characteristic of the cells found in LCH. The two major diseases among the class II histiocytoses have indistinguishable pathologic findings. One is **familial erythrophagocytic lymphohistiocytosis** (FEL), which is the only inherited form of histiocytosis and is autosomal recessive. Most recently, several specific gene mutations underlying FEL have been discovered. The other is the **infection-associated hemophagocytic syndrome** (IAHS). Both diseases are characterized by disseminated lesions that involve many organ systems. The lesions are characterized by infiltration of the involved organ with activated phagocytic macrophages and lymphocytes, and the diseases are grouped together under the term **hemophagocytic lymphohistiocytosis** (HLH).

The mixed cellular lesions of both the class I and class II histiocytoses suggest that these may be disorders of immune regulation, resulting from either an unusual and unidentified antigenic stimulation or an abnormal and somehow defective cellular immune response. In fact, the genetic defect in some cases of FEL has been identified as a defect in perforin, the effector molecule of cytotoxic lymphocytes whose function has been found to be inhibited in FEL. In contrast, the class III histiocytoses are unequivocal malignancies of cells of monocyte- macrophage lineage. By this definition, acute monocytic leukemia and true malignant histiocytosis are included among the class III histiocytoses (see Chapter 487). The existence of neoplasms of Langerhans cells is controversial. Some cases of LCH demonstrate clonality.

CLASS I HISTIOCYTOSES

Clinical Manifestations.

LCH has an extremely variable presentation. The skeleton is involved in 80% of patients and may be the only affected site, especially in children older than 5 yr of age. Bone lesions may be single or numerous and are seen most commonly in the skull (Fig. 499–1). They may be asymptomatic or associated with pain and local swelling. Involvement of the spine may result in collapse of the vertebral body, which can be seen radiographically, and may cause secondary compression of

Figure 499-1 Two skull radiographs from patients with LCH. *Left*, The patient was older than 2 yr of age and had involvement limited to isolated bone lesions *(arrows)*. She had a good recovery. *Right,* The patient was younger than 2 yr of age and had extensive bone disease *(arrows)*, febrile course, anemia, severe skin eruption, generalized lymphadenopathy, hepatosplenomegaly, pulmonary infiltrates, and a fatal outcome despite antitumor chemotherapy. These patients represent opposite ends of the clinical spectrum of LCH.

the spinal cord. In flat and long bones, osteolytic lesions with sharp borders occur and no evidence exists of reactive new bone formation (until the lesions begin to heal). Lesions that involve weight-bearing long bones may result in pathologic fractures. Chronically draining, infected ears are commonly associated with destruction in the mastoid area. Bone destruction in the mandible and maxilla may result in teeth that, on radiographs, appear to be free floating. With response to therapy, healing may be complete.

Skin involvement occurs in about 50% of patients at some time during their course (usually, a seborrheic dermatitis of the scalp or diaper region). The lesions may spread to involve the back, palms, and soles. The exanthem may be petechial or hemorrhagic, even in the absence of thrombocytopenia. Localized or disseminated lymphadenopathy is present in approximately 33% of patients. Hepatosplenomegaly occurs in approximately 20% of patients. Various degrees of hepatic malfunction may occur, including jaundice and ascites.

Exophthalmos, when present, is often bilateral and is caused by retro-orbital accumulation of granulomatous tissue. Gingival mucous membranes may be involved with infiltrative lesions that appear superficially like candidiasis. In 10–15% of patients, pulmonary infiltrates are found on radiography. The lesions may vary from diffuse fibrosis and disseminated nodular infiltrates to diffuse cystic changes. Rarely, pneumothorax may be a complication. If the lungs are severely involved, tachypnea and progressive respiratory failure may result.

Pituitary dysfunction or hypothalamic involvement may result in growth retardation. In addition, patients may have diabetes insipidus; patients suspected of having LCH should demonstrate the ability to concentrate their urine before going to the

operating room for a biopsy. Rarely, panhypopituitarism may occur. Primary hypothyroidism due to thyroid gland infiltration may also occur.

Patients who are affected more severely may have systemic manifestations, including fever, weight loss, malaise, irritability, and failure to thrive. Bone marrow involvement may cause anemia and thrombocytopenia. Two uncommon but serious and unusual manifestations of LCH are hepatic involvement (leading to cirrhosis) and a peculiar central nervous system (CNS) involvement characterized by ataxia, dysarthria, and other neurologic symptoms. Associated with multisystem disease, hepatic involvement is frequently already present at the time of diagnosis. In contrast, the CNS involvement, which is progressive, histopathologically characterized by gliosis, and for which no treatment is known, may be observed only many years after the initial diagnosis of LCH, which may have consisted only of mild bone disease. Striking is that neither of these manifestations evidence Langerhans cells or Birbeck granules.

After tissue biopsy, which is diagnostic and easiest to perform on skin or bone lesions, a thorough clinical and laboratory evaluation should be undertaken. This should include a series of studies in all patients (complete blood cell count, liver function tests, coagulation studies, skeletal survey, chest radiograph, and measurement of urine osmolality). In addition, detailed evaluation of any organ system that has been shown to be involved by physical examination or by these studies should be performed to establish the extent of disease before initiation of treatment.

Treatment and Prognosis.

The clinical course of single-system disease (usually, bone, lymph node, or skin) is generally benign, with a high chance of spontaneous remission. Therefore, treatment should be minimal and should be directed at arresting the progression of a lesion (e.g., a bone lesion) that could result in permanent damage before it resolves spontaneously. Curettage or low-dose local radiation therapy (5–6 Gy) may accomplish this goal. Multisystem disease, in contrast, should be treated with systemic multiagent chemotherapy. Several different regimens have been proposed, but a central element is the inclusion of either vinblastine or etoposide, which have been found to be very effective in treating LCH. Based on the most recent findings, treatment of multisystem LCH includes therapy with multiple agents, designed to reduce reactivation of disease and long-term consequence. The response rate to therapy, contrary to previous opinion, may be high, especially if the diagnosis is accurately and expeditiously ascertained. Experimental therapies, suggested only for unresponsive disease (frequently very young children with multisystem disease who have not responded to initial treatment), include immunosuppressive therapy with cyclosporine/antithymocyte globulin and possibly certain new agents and modalities, such as 2-chlorodeoxyadenosine and stem cell transplantation. Current treatment approaches and experimental protocols for both class I and class II histiocytoses can be obtained at *www.histio.org/society*, the website for the Histiocyte Society.

CLASS II HISTIOCYTOSES

Clinical Manifestations.

The major forms of class II histiocytosis, FEL and IAHS, have a remarkably similar presentation, consisting of a generalized disease process, most often with fever, weight loss, and irritability. FEL is also characterized by severe immunodeficiency. Children with FEL are always younger than 4 yr of age; children with IAHS may present at an older age. Physical examination frequently reveals hepatosplenomegaly and symptoms of CNS involvement (with an aseptic meningitis, the cerebrospinal fluid cells are the same phagocytic macrophages as found in the peripheral blood or bone marrow). As in the class I histiocytoses, the diagnosis rests on the pathologic findings. Associated laboratory findings in both forms of class II histiocytosis include hyperlipidemia, hypofibrinogenemia, elevated levels of hepatic enzymes, extremely elevated levels of circulating soluble interleukin-2 receptors released by the activated lymphocytes, and sometimes cytopenias. No absolute clinical or laboratory distinction can be made between FEL and IAHS. Without a genetic marker for FEL at present, the distinction can definitively be made only by a positive family history for other affected children.

Treatment and Prognosis.

The diagnostic distinction between FEL and IAHS can sometimes be based on the acute onset of IAHS in the presence of a documented infection. In this case, treatment of the underlying infection, coupled with supportive care, is critical. If the diagnosis is made in a setting of iatrogenic immunodeficiency, immunosuppressive treatment should be withdrawn and supportive care should be instituted along with specific therapy for underlying infection. When FEL is diagnosed or suspected and when an infection cannot be documented, therapy currently includes etoposide and immunosuppressive therapy. Nevertheless, even with chemotherapy, FEL remains uniformly fatal. However, allogeneic bone marrow transplantation may be effective in curing a significant fraction of patients with FEL and provides hope for the outcome of this disease.

In contrast, in IAHS, when an infection can be documented and effectively treated, the prognosis is good without any other specific treatment. When a treatable infection cannot be documented (as is the case in most patients presumed to have IAHS), the prognosis is as poor as that of FEL; and an identical chemotherapeutic approach, including etoposide, is recommended. It is theorized that, by its cytotoxic effect on macrophages, etoposide interrupts cytokine production, the hemophagocytic process, and the accumulation of macrophages, all of which may contribute to the pathogenesis of IAHS. A broad spectrum of infectious agents, viruses (e.g., cytomegalovirus, Epstein-Barr virus, human herpesvirus 6), fungi, protozoa, and bacteria may trigger IAHS, usually in the setting of immunodeficiency. A thorough evaluation for infection should be undertaken in immunodeficient patients with hemophagocytosis. Rarely, the same syndrome may be identified in conjunction

with a neoplasm (e.g., leukemia); in this case, treatment of the underlying disease causes resolution of the hemophagocytosis. In some patients, interferon and intravenous immunoglobulin have been effective.

CLASS III HISTIOCYTOSES

By this definition, acute monocytic leukemia and true malignant histiocytosis are included among the class III histiocytoses (see Chapter 487).

Part 22 - Nephrology

Section 1 - *Glomerular Disease*

Ira D. Davis
Ellis D. Avner

Chapter 500 - Introduction to Glomerular Diseases

500.1 Anatomy of the Glomerulus

The kidneys lie in the retroperitoneal space slightly above the level of the umbilicus. They range in length and weight, respectively, from approximately 6?cm and 24?g in a full-term newborn to 12?cm or more and 150?g in an adult. The kidney (Fig. 500–1) has an outer layer, the cortex, which contains the glomeruli, proximal and distal convoluted tubules, and collecting ducts, and an inner layer, the medulla, which contains the straight portions of the tubules, the loops of Henle, the vasa recta, and the terminal collecting ducts (Fig. 500–2).

The blood supply to each kidney usually consists of a main renal artery that arises from the aorta; multiple renal arteries may occur. The main artery divides into segmental branches within the medulla and these into interlobar arteries that pass through the medulla to the junction of the cortex and medulla. At this point, the interlobar arteries branch to form the arcuate arteries, which run parallel to the surface of the kidney. Interlobular arteries originate from the arcuate arteries and give rise to the afferent arterioles of the glomeruli. Specialized muscle cells in the wall of the afferent arteriole and the macula densa within the distal tubule next to the glomerulus form the

Figure 500.1-1 Gross morphology of the renal circulation. (From Pitts RF: *Physiology of the Kidney and Body Fluids*, 3rd ed. Chicago, Year Book Medical Publishers, 1974.)

juxtaglomerular apparatus that controls the secretion of renin. The afferent arteriole divides into the glomerular capillary network, which then merges into the efferent arteriole (Fig. 500–3). The efferent arterioles of glomeruli next to the medulla (juxtamedullary glomeruli) are larger than those in the outer cortex and provide the blood supply (vasa recta) to the tubules and medulla.

Each kidney contains approximately 1 million nephrons (glomeruli and associated tubules). In humans, formation of nephrons is complete at birth, but functional maturation with tubular growth and elongation continues during the first decade of life. Because new nephrons cannot be formed after birth, progressive loss of nephrons may lead to renal insufficiency.

The glomerular network of specialized capillaries serves as the filtering mechanism of the kidney. The glomerular capillaries are lined by endothelial cells (Fig. 500–4) having very thin cytoplasm that contains many holes (fenestrations). The glomerular basement membrane (GBM) forms a continuous layer between the endothelial and mesangial cells on one side and the epithelial cells on the other. The membrane has three layers: (1) a central electron-dense lamina densa; (2) the lamina rara interna, which lies between the lamina densa and the endothelial cells;

Figure 500.1-2 Comparison of the blood supplies of cortical and juxtamedullary nephrons. (From Pitts RF: *Physiology of the Kidney and Body Fluids*, 3rd ed. Chicago, Year Book Medical Publishers, 1974.)

Figure 500.1-3 Schematic depiction of the glomerulus and surrounding structures.

Figure 500.1-4 Electron micrograph of the normal glomerular capillary (Cap) wall demonstrating the endothelium (En) with its fenestrations (f), the glomerular basement membrane (B) with its central dense layer, the lamina densa (LD) and adjoining lamina rara interna (LRI) and externa (LRE; *long arrow*) and the epithelial cell foot processes (fp) with their thick cell coat (c). The glomerular filtrate passes through the endothelial fenestrae, crosses the basement membrane, and passes through the filtration slits *(short arrow)* between the epithelial cell foot processes to reach the urinary space (US). (×60,000.) J is the junction between two endothelial cells. (From Farquhar MG, Kanwar YS: Functional organization of the glomerulus: State of the science in 1979. In Cummings NB, Michael AF, Wilson CB [editors]: *Immune Mechanisms in Renal Disease*. New York, Plenum, 1982. Reprinted by permission.)

and (3) the lamina rara externa, which lies between the lamina densa and the epithelial cells. The visceral epithelial cells cover the capillary and project cytoplasmic “foot processes,” which attach to the lamina rara externa. Between the foot processes are spaces or filtration slits. The mesangium (mesangial cells and matrix) lies between the glomerular capillaries on the endothelial cell side of the GBM and forms the medial part of the capillary wall. The mesangium may serve as a supporting structure for the glomerular capillaries and probably has a role in the regulation of glomerular blood flow and filtration and in the removal of macromolecules (such as immune complexes) from the glomerulus, either through intracellular phagocytosis or by transport through intercellular channels to the juxtaglomerular region. Bowman capsule, which surrounds the glomerulus, is composed of (1) a basement membrane, which is continuous with the basement membranes of the glomerular capillaries and the proximal tubules, and (2) the parietal epithelial cells, which are continuous with the visceral epithelial cells.

500.2 Glomerular Filtration

As the blood passes through the glomerular capillaries, the plasma is filtered through the glomerular capillary walls. The ultrafiltrate, which is cell free, contains all the substances in the plasma (electrolytes, glucose, phosphate, urea, creatinine, peptides, low molecular weight proteins) except proteins (like albumin and the globulins) having a molecular weight of 68,000 or more. The filtrate is collected in Bowman space and enters the tubules, where its composition is modified by solute and fluid secretion and absorption in accordance with tightly regulated homeostatic mechanisms until it leaves the kidney as urine.

Glomerular filtration is the net result of opposing forces across the capillary wall. The force for ultrafiltration (glomerular capillary hydrostatic pressure) stems from the systemic arterial pressure, as modified by the tone of the afferent and efferent arterioles. The major force opposing ultrafiltration is the glomerular capillary oncotic pressure, which is created by the gradient between the high concentration of plasma proteins within the capillary and the almost protein-free ultrafiltrate in Bowman space. Filtration may be modified by the rate of glomerular plasma flow, the hydrostatic pressure within Bowman space, and the permeability of the glomerular capillary wall.

Although glomerular filtration begins around the 9th wk of fetal life, kidney function is not necessary for normal intrauterine homeostasis because the placenta serves as the major excretory organ. After birth, the glomerular filtration rate (GFR) increases until growth ceases toward the end of the 2nd decade of life. To facilitate the comparison of the GFRs of children and adults, GFR is standardized to the surface area (1.73?m^2) of a 70-kg adult. Even after correction for surface area, the GFR of a child does not approximate adult values until the 3rd yr of life (Fig. 500–5).

The GFR may be estimated by measurement of the serum creatinine level (Fig. 500–6). Creatinine is derived from muscle metabolism. Its production is relatively constant, and its excretion is primarily through glomerular filtration, although tubular secretion may become important in renal insufficiency. In contrast to the concentration of blood urea nitrogen, which is affected by state of hydration and nitrogen balance, the serum creatinine level is primarily influenced by the level of glomerular function. The serum creatinine is of value only in estimating the GFR in the steady state. For example, a patient may have a normal creatinine level without effective renal function very shortly after the onset of acute renal failure with anuria. In this clinical setting, serum creatinine may be an insensitive measure of decreased renal function, because its level does not rise above normal until the GFR falls by

30–40%.

The precise measurement of the GFR is accomplished by quantitating the “clearance” of a substance that is freely filtered across the capillary wall and that is neither reabsorbed nor secreted by the tubules. The clearance (C_s) of such a substance is

Figure 500.2-5 Changes in the normal value of the glomerular filtration rate, as measured by the creatinine clearance (C_{CR}), when standardized to mL/min/1.73?m² of body surface area. The *solid line* depicts the mean value, and the *shaded area* includes two standard deviations. (Reprinted by permission of the publishers from McCrory W: *Developmental Nephrology*. Cambridge, MA, Harvard University Press. Copyright © 1972 by the President and Fellows of Harvard College.)

that volume of plasma that, when completely “cleared” of the contained substance, would yield a quantity of that substance equal to that excreted in the urine over a specified time. The clearance is represented by the following formula:

where C_s equals the clearance of substance s, U_s reflects the urinary concentration of s, V represents the urinary flow rate, and P_s equals the plasma concentration of s. To correct the clearance for body surface area, the formula is

Figure 500.2-6 The serum creatinine in relation to age. (Reprinted by permission of the publishers from McCrory W: *Developmental Nephrology*. Cambridge, MA, Harvard University Press. Copyright © 1972 by the President and Fellows of Harvard College.)

The GFR is optimally measured by the clearance of inulin, a fructose polymer having a molecular weight of approximately 5,000. Because the inulin clearance technique is cumbersome, the GFR is commonly estimated by the clearance of endogenous creatinine. When the GFR is relatively normal, the creatinine clearance closely approximates the inulin clearance. As the GFR declines, an increasing proportion of the total creatinine in the urine is secreted by tubules, resulting in a creatinine clearance that progressively overestimates the actual GFR. Therefore, changes in renal function should be monitored by serum creatinine concentration when the serum creatinine level exceeds 2.0?mg/dL (180?µmol/L).

The absence of plasma proteins larger than the size of albumin from the glomerular filtrate confirms the effectiveness of the glomerular capillary wall as a filtration barrier. Major factors restricting the filtration of these and other macromolecules include their size and their ionic charge.

Clearance studies of macromolecules in animals have shown no restriction to the filtration of molecules up to the size of inulin. As size increases farther, filtration diminishes progressively, approaching zero for substances the size of albumin. Morphologic studies suggest that the size-selective filtration barrier resides within the GBM.

The endothelial cell, basement membrane, and epithelial cell of the glomerular capillary wall possess strong negative ionic charges. These anionic charges are a consequence of two negatively charged moieties: proteoglycans (heparan sulfate) and glycoproteins containing sialic acid. Proteins in the blood have a relatively low isoelectric point and carry a net negative charge. Consequently, they are repelled by the negatively charged sites in the glomerular capillary wall, thus restricting filtration.

500.3 Glomerular Diseases

Pathogenesis.

Glomerular injury may be a result of genetic, immunologic, or coagulation disorders. Genetic disorders of the glomerulus result from (1) mutations in the exons of DNA encoding transcriptional units that undergo translation in the ribosomes forming proteins located within the glomerulus, interstitium, or tubular epithelium; (2) mutations in the regulatory genes controlling DNA transcription; (3) abnormal post-transcriptional modification of RNA transcripts; or (4) abnormal post-translational modification of proteins. Immunologic injury is the most common cause and results in *glomerulonephritis*, which is both a generic term for several diseases and a histopathologic term signifying inflammation of the glomerular capillaries. Evidence that glomerulonephritis is caused by immunologic injury includes (1) morphologic and immunopathologic similarities to experimental immune-mediated glomerulonephritis; (2) the demonstration of immune reactants (immunoglobulin and complement components) in glomeruli; and (3) abnormalities in serum complement and the finding of autoantibodies (e.g., anti-GBM) in some of these diseases. There appear to be two major mechanisms of immunologic injury: (1) localization of circulating antigen-antibody immune complexes and (2) interaction of antibody with local antigen in situ. In the latter circumstance, the antigen may be a normal component of the glomerulus (e.g., the noncollagenous domain [NC-1] of type IV collagen, which is the putative antigen in human anti-GBM nephritis) or an antigen that has been deposited in the glomerulus.

In immune complex–mediated diseases, antibody is produced against and combines with a circulating antigen that is usually unrelated to the kidney. The immune complexes accumulate in glomeruli and activate the complement system, leading to immune injury. Experimental studies suggest that the complexes are formed in the circulation and deposited in the kidney. Acute serum sickness in rabbits is produced by a single intravenous injection of bovine albumin. Within 1 wk after injection, a rabbit produces antibody against bovine albumin, while the antigen remains in the blood in high concentration. As antibody enters the circulation, it forms immune complexes with antigen. Although the amount of antigen in the circulation exceeds that of antibody (antigen excess), the complexes formed are small, remain soluble in the circulation, and are deposited in glomeruli. The processes involved in glomerular localization are not well understood but include attributes of the complex (concentration, charge, size), characteristics of the glomerulus (mesangial trapping, negatively charged capillary wall), hydrodynamic forces, and the influence of various mediators (angiotensin II, prostaglandins).

With deposition of immune complexes in glomeruli, rabbits develop an acute proliferative glomerulonephritis. Immunofluorescence microscopy demonstrates granular ("lumpy-bumpy") deposits containing immunoglobulin and complement in the glomerular capillary wall. Electron microscopic studies show these deposits to be on the epithelial side of the GBM and in the mesangium. For the next few days, as additional antibody enters the circulation, the antigen is ultimately removed from the circulation and the glomerulonephritis subsides. In rabbits, complement does not participate in the capillary injury, which is largely related to influx of macrophages. In other models, complement has a role in capillary injury.

An example of in situ antigen-antibody interaction is anti-GBM antibody disease, in which antibody reacts with antigen(s) of the GBM. Immunopathologic studies reveal linear deposition of immunoglobulin and complement on the GBM, similar to that in Goodpasture disease and certain types of rapidly progressive glomerulonephritis.

The inflammatory reaction that follows immunologic injury results from activation of one or more mediator pathways. The most important of these is the complement system, which has two initiating sequences: (1) the classic pathway, which is activated by antigen-antibody immune complexes, and (2) the alternative or properdin pathway, which is activated by polysaccharides and endotoxin. These pathways converge at C3; from that point on, the same sequence leads to lysis of cell membranes (see Fig. 123–1). The major noxious products of complement activation are produced after activation of C3 and include anaphylatoxin (which stimulates contractile proteins within vascular walls and increases vascular permeability) and chemotactic factors (C5a) that direct neutrophils and perhaps macrophages to the site of complement activation, where the cells release substances that damage vascular cells and basement membranes.

The coagulation system may be activated directly, after endothelial cell injury, which bares the thrombogenic subendothelial layer (initiating the coagulation cascade), or indirectly, after complement activation. Fibrin deposits may occur within glomerular capillaries or within Bowman space in crescents. Activation of the coagulation process may activate the kinin system, which also produces chemotactic and anaphylatoxin-like factors.

Pathology.

The glomerulus may be injured by several mechanisms but has only a limited number of histopathologic responses; accordingly, different disease states may produce similar microscopic changes.

Proliferation of glomerular cells occurs in most forms of glomerulonephritis and may be generalized, involving all glomeruli, or focal, involving only some glomeruli while sparing others. Within a single glomerulus, proliferation may be diffuse, involving all parts of the glomerulus, or segmental, involving only some areas but not others. Proliferation commonly involves the endothelial and mesangial cells and is frequently associated with an increase in the mesangial matrix. Mesangial proliferation may result from immune complex deposition within the mesangium. The resultant increase in cell size and number, and in mesangial matrix, may increase glomerular size and narrow the lumens of glomerular capillaries, leading to renal insufficiency.

Crescent formation in Bowman space (capsule) is a result of proliferation of parietal epithelial cells. Crescents develop in several forms of glomerulonephritis (termed *rapidly progressive*) and are thought to be a response to fibrin deposited in Bowman space. New crescents contain fibrin, the proliferating epithelial cells of Bowman space, basement membrane–like material produced by these cells, and macrophages that may have a role in the genesis of glomerular injury. In days to weeks, the crescent is invaded by connective tissue (fibroepithelial crescent); this generally results in glomerular obsolescence. Crescent formation is frequently associated with glomerular cell death. The necrotic glomerulus has a characteristic eosinophilic appearance and usually contains nuclear remnants. Crescent formation is usually associated with generalized proliferation of the mesangial cells and with either immune complex or anti-GBM antibody deposition in the glomerular capillary wall.

In addition to proliferation, certain forms of acute glomerulonephritis show glomerular *exudation of blood cells*, including neutrophils, eosinophils, basophils, and mononuclear cells. The thickened appearance of GBM may result from a true *increase in the width of the membrane* (as seen in membranous glomerulopathy), from massive deposition of immune complexes that have staining characteristics similar to the membrane (as seen in systemic lupus erythematosus), or from the interposition of mesangial cells and matrix into the subendothelial space between the endothelial cells and the membrane. The latter may give the basement membrane a split appearance, as seen in type I membranoproliferative glomerulonephritis and other diseases.

Sclerosis refers to the presence of scar tissue within the glomerulus. Occasionally, pathologists use this term to refer to an increase in mesangial matrix.

Tubulointerstitial fibrosis is present in all patients with glomerular disease who develop progressive renal injury. This fibrosis is initiated by injury to the renal tubules resulting in mononuclear cell infiltrates that release soluble factors that have

fibrosis-promoting effects. Additionally, matrix proteins of the renal interstitium begin to accumulate, leading to eventual destruction of renal tubules and peritubular capillaries.

Section 2 - *Conditions Particularly Associated with Hematuria*

Ira D. Davis
Ellis D. Avner

Chapter 501 - Clinical Evaluation of the Child with Hematuria

Hematuria is defined as the presence of at least five red blood cells (RBCs) in the urine and occurs with a prevalence of 0.5–2.0% among school-aged children. Quantitative studies demonstrate that the normal child aged 4–12 yr excretes more than 100,000 RBCs per 12-hr period and that this increases with fever and/or exercise. In the clinical setting, qualitative estimates are provided by a urinary “dipstick” that uses a peroxidase-like chemical reaction between hemoglobin (or myoglobin) and a chemical indicator compound impregnated on the dipstick. Chemstrip (Boehringer Mannheim), a common commercially available dipstick, is capable of detecting 3–10 RBCs per microliter of unspun urine with significant hematuria suggested by the presence of more than 50 RBCs/µL. False-negative results may occur in the presence of formalin (used as a urine preservative) or high urinary concentrations of ascorbic acid. False-positive results may be seen in the presence of menstrual blood, alkaline urine with a pH greater than 9, or contamination with oxidizing agents used to clean the perineum before obtaining a specimen. Microscopic analysis of 10–15?mL of fresh centrifuged urine is essential in confirming the diagnosis of hematuria suggested by a positive dipstick. Screening urinalyses should be obtained during well child care visits at 5 yr and once during the second decade of life (see Chapter 5).

Red urine *without RBCs* is seen in a number of conditions (Box 501–1). Heme-positive urine without RBCs is caused by the presence of either hemoglobin or myoglobin. *Hemoglobinuria* without hematuria may occur in the presence of hemolytic anemia. *Myoglobinuria* without hematuria occurs in the presence of rhabdomyolysis syndrome resulting from skeletal muscle injury and is generally associated with a fivefold increase in the plasma concentration of creatine kinase. *Rhabdomyolysis* may occur secondary to viral disease, crush injury, severe electrolyte abnormalities (i.e., hypernatremia, hypophosphatemia), hypotension, disseminated intravascular coagulation, and prolonged seizures. Heme-negative

urine may appear red, cola colored, or burgundy, owing to ingestion of various drugs or food dyes, whereas dark brown (or black) urine may result from various urinary metabolites.

Evaluation of the child with hematuria begins with a careful history, physical examination, and urinalysis. This information is used to determine the level of hematuria (i.e., upper vs. lower urinary tract) and to determine the urgency of the evaluation

based on the symptomatology. In addition, special consideration needs to be given to family history, identification of anatomic abnormalities/malformation syndromes, and presence of gross hematuria.

Causes of hematuria are listed in Box 501–2 . Upper urinary tract sources of hematuria originate within the nephron (i.e., glomerulus, convoluted/collecting tubules and interstitium). Lower urinary tract sources of hematuria originate from the pelvocalyceal system, ureter, bladder, or urethra. Hematuria from within the glomerulus is frequently associated with brown, cola-colored, or burgundy urine, proteinuria exceeding 100?mg/dL via dipstick, red blood cell casts, and deformed urinary RBCs. Hematuria originating within the convoluted or collecting tubules may be associated with the presence of leukocyte or renal tubular epithelial cell casts. On the other hand, lower urinary tract sources of hematuria may be associated with gross hematuria, terminal hematuria (i.e., onset of gross hematuria occurs at the end of the urine stream), blood clots, normal urinary RBC morphology, and minimal proteinuria on dipstick (i.e. <100?mg/dL).

Patients with hematuria may present with a number of symptoms suggestive of specific disorders. Tea or cola-colored urine,

facial/body edema, hypertension, and oliguria suggest the acute nephritic syndrome. Diseases commonly presenting as acute nephritic syndrome include postinfectious glomerulonephritis, IgA nephropathy, membranoproliferative glomerulonephritis, Henoch-Schönlein purpura nephritis (HSP), systemic lupus erythematosus (SLE) nephritis, Wegener granulomatosis, microscopic polyarteritis nodosa, Goodpasture syndrome, and hemolytic-uremic syndrome. A history of recent upper respiratory, skin, or gastrointestinal infection suggests acute glomerulonephritis, hemolytic-uremic syndrome, or HSP. Rash and joint complaints point toward HSP or SLE. Frequency, dysuria, and unexplained fevers suggest a urinary tract infection whereas renal colic suggests nephrolithiasis. A flank mass may signal hydronephrosis, cystic disease, renal vein thrombosis, or tumor. Hematuria associated with headache, visual changes, epistaxis, or congestive heart failure suggests significant hypertension. Finally, patients with a history of trauma require immediate evaluation. Child abuse must always be suspected in the child presenting with unexplained bruising and hematuria.

A careful family history is crucial in the initial assessment of the child with hematuria in view of numerous genetic causes of renal disorders. Hereditary glomerular diseases include hereditary nephritis (Alport syndrome), thin glomerular basement membrane disease, SLE nephritis, and IgA nephropathy (Berger disease). Other renal disorders with a hereditary component include polycystic kidney disease, urolithiasis, and sickle cell disease/trait.

Physical examination is critical in assessing the cause of hematuria. Hypertension, body edema, hepatosplenomegaly, or signs of congestive heart failure suggest acute glomerulonephritis. Several malformation syndromes are associated with renal disease including VATER (*v*ertebral body anomalies, *a*nal atresia, *t*racheo-*e*sophageal fistula and *r*enal dysplasia) syndrome. Abdominal masses may be caused by posterior urethral valves, ureteropelvic junction obstruction, polycystic kidney disease, or Wilms tumor. Hematuria seen in patients with neurologic or cutaneous abnormalities may be the result of renal cystic disease or tumors associated with several syndromes, including tuberous sclerosis, von Hippel-Lindau syndrome, and Zellweger (cerebrohepatorenal) syndrome. Finally, anatomic abnormalities of the external genitals may be associated with renal disease.

Patients with gross hematuria present additional challenges because of the associated parental anxiety. This entity must be distinguished from *urethrorrhagia,* which refers to urethral bleeding (in the absence of urine) associated with dysuria and blood spots on underwear after voiding. This condition, which often occurs in prepubertal boys at intervals several months apart over a period of many years, has a benign self-limited course. Common causes of gross hematuria are listed in Box 501–3 . The most common cause of gross hematuria is either documented or suspected urinary tract infections. Less than 10% of patients have evidence of glomerulonephritis. Recurrent episodes of gross hematuria suggest IgA nephropathy, Alport syndrome, thin glomerular basement membrane disease, hypercalciuria, or urolithiasis.

A general approach to the laboratory and radiologic evaluation of the patient with glomerular or extraglomerular hematuria is outlined in Figure 501–1 . Asymptomatic patients with isolated microscopic hematuria should not undergo diagnostic evaluation until at least two additional urine specimens collected over a 1–2 wk period demonstrate an abnormal number of RBCs. This will reduce the number of unnecessary evaluations by tenfold to a hundredfold.

The child with persistent asymptomatic isolated microscopic hematuria of greater than 2 wk duration poses a dilemma as to the extent to which one should pursue diagnostic evaluation. It is recommended that the initial evaluation of these children includes a urine culture followed by a spot urine for calcium and creatinine

concentration in culture-negative patients. In African-American patients, a sickle cell screen should be included. Renal and bladder ultrasonography should be considered to rule out structural lesions such as tumor, cystic disease, hydronephrosis, or urolithiasis. Ultrasonography of the urinary tract is most informative in patients presenting with gross hematuria, abdominal pain, flank pain, or trauma. If these initial studies are normal, assessment of serum creatinine and electrolytes is recommended.

The finding of certain hematologic abnormalities may narrow the differential diagnosis. Anemia in this setting may be caused by (1) intravascular dilution secondary to hypervolemia associated with acute renal failure; (2) decreased RBC production in chronic renal failure; (3) hemolysis from hemolytic-uremic syndrome or SLE; and (4) blood loss from pulmonary hemorrhage as seen in Goodpasture syndrome or melena in patients with Henoch-Schönlein purpura or hemolytic-uremic syndrome. Inspection of the peripheral blood smear may reveal a microangiopathic process as seen in the hemolytic-uremic syndrome, renal vein thrombosis, vasculitis, and SLE. In the latter, the presence of autoantibodies may result in a positive Coombs test, the presence of antinuclear antibody, leukopenia, and multisystem disease. Thrombocytopenia may result from decreased platelet production (malignancies) or increased platelet consumption (SLE, idiopathic thrombocytopenic purpura, hemolytic-uremic syndrome, renal vein thrombosis). Although urinary RBC morphology may be normal with lower tract bleeding and dysmorphic from glomerular bleeding, cell morphology does not reliably correlate with the site of hematuria. The best screening test for a bleeding diathesis is a thorough history. Coagulation studies are not routinely obtained unless personal or family history suggests a bleeding tendency.

A voiding cystourethrogram is only required in patients with a urinary tract infection, renal scarring, hydroureter, or pyelocaliectasis. Cystoscopy, an unnecessary and costly procedure in patients with hematuria that carries the associated risks of anesthesia, should be reserved for the evaluation of the rare child with a bladder mass noted on ultrasound, urethral abnormalities caused by trauma, posterior urethral valves, or tumor. Unilateral gross hematuria identified by cystoscopy is rarely encountered in the pediatric patient.

Referral to a pediatric nephrologist is recommended for patients with nephritis (i.e., glomerulonephritis and tubulointerstitial nephritis), hypertension, renal insufficiency, urolithiasis/nephrocalcinosis, or a family history of renal disease such as polycystic kidney disease or hereditary nephritis. Renal biopsy is indicated for children with persistent microscopic hematuria or recurrent gross hematuria associated with decreased renal function, proteinuria, or hypertension.

Children with persistent asymptomatic isolated hematuria and a normal evaluation should have their serum creatinine values checked annually and their blood pressure and urine checked every 3 mo until the hematuria resolves. Diagnoses to be considered in this situation include resolving postinfectious glomerulonephritis, thin basement membrane disease, IgA nephropathy, or heavy exercise/trauma. Referral to a pediatric nephrologist should be considered for patients with persistent asymptomatic hematuria greater than 1 yr duration.

Chapter 502 - Isolated Glomerular Diseases with Recurrent Gross Hematuria

Approximately 10% of children with gross hematuria have either an acute or chronic form of glomerulonephritis that may be associated with a systemic illness. The gross hematuria, which is usually characterized by brown or cola-colored urine, may be painless or associated with vague flank or abdominal pain. Presentation with gross hematuria is common within 1–2 days after the onset of an apparent viral upper respiratory tract infection in many forms of glomerulonephritis, such as IgA nephropathy, and typically resolves within 5 days. This relatively short period contrasts to a latency period of 7–21 days occurring between the onset of a streptococcal pharyngitis or impetigo skin infection and the development of acute glomerulonephritis. Gross hematuria in these circumstances may last as long as 4–6 wk. Gross hematuria may also be seen in children with glomerular basement membrane (GBM) disorders such as hereditary nephritis (i.e., Alport syndrome) and thin GBM disease. However, these glomerular diseases may also present as microscopic hematuria and/or proteinuria without gross hematuria.

502.1 IgA Nephropathy (Berger Nephropathy)

IgA nephropathy is the most common chronic glomerular disease worldwide. It is characterized by a predominance of IgA within mesangial deposits of the glomerulus in the absence of systemic diseases such as systemic lupus erythematosus or Henoch-Schönlein purpura. Other diseases with prominent IgA mesangial deposition include rheumatoid arthritis, ankylosing spondylitis, Reiter syndrome, and hepatic cirrhosis.

Pathology and Pathologic Diagnosis.

On light microscopy, focal and segmental mesangial proliferation and increased mesangial matrix are seen in the glomerulus (Fig. 502–1). Some children display generalized mesangial proliferation which may be associated with crescent formation and scarring. IgA is the predominant immunoglobulin deposited in the mesangium (Fig. 502–2), but lesser amounts of IgG, IgM, C3, and properdin are common. Electron microscopic studies demonstrate electron-dense mesangial deposits in most patients. Electron-dense deposits may also be seen in the subendothelial and

subepithelial regions of the GBM.

Although the pathogenesis remains to be elucidated, IgA nephropathy is an immune complex disease that appears to be caused by abnormalities in the IgA immune system. Furthermore, familial clustering of IgA nephropathy cases suggests the importance of genetic factors. Genetic studies using genome-wide linkage analysis suggest linkage of IgA nephropathy to 6q22-23 in multiplex IgA nephropathy kindreds.

Clinical and Laboratory Manifestations.

A majority of children with IgA nephropathy in the United States and Europe present with gross hematuria whereas microscopic hematuria and/or proteinuria is a more common presentation in Japan. Other types of presentation include acute nephritic syndrome, nephrotic syndrome, or a combined nephritic-nephrotic syndrome. Also, IgA nephropathy is seen more often in males than in females. Gross hematuria often occurs in association with an upper respiratory or gastrointestinal infection and may be associated with loin pain. Proteinuria is frequently less than 1,000 mg/24?hr in patients with asymptomatic microscopic hematuria. Mild to moderate hypertension is most often seen in patients with nephritic or nephrotic syndrome but is rarely severe enough to result in hypertensive emergencies. Normal serum levels of C3 in IgA nephropathy help to distinguish this disorder from poststreptococcal glomerulonephritis. Serum IgA levels have no diagnostic value because they are elevated in only 15% of patients.

Prognosis and Treatment.

Although IgA nephropathy does not lead to significant kidney damage in most children, progressive disease develops in 20–30% of children at 15–20 yr after disease onset. Therefore, most children with IgA nephropathy will not display progressive renal dysfunction until adulthood, prompting the need for careful long-term follow-up. Poor prognostic indicators include persistent hypertension, diminished renal function, and heavy or prolonged proteinuria. A worse prognosis is suggested by histologic evidence of diffuse mesangial proliferation, extensive glomerular crescents, glomeruloscle

Figure 502.1-2 Immunofluorescence microscopy of the biopsy from a child having recurrent episodes of gross hematuria demonstrating mesangial deposition of IgA. (×250.)

rosis, and tubulointerstitial changes, including inflammation and fibrosis.

The primary treatment of IgA nephropathy is proper blood pressure control. A controlled study in adults with IgA nephropathy suggests that fish oil, which contains anti-inflammatory omega-3 fatty acids, may decrease the rate of renal progression. Immunosuppressive therapy with corticosteroids or more intensive, multidrug regimens may be beneficial in some patients. The benefits of angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists in reducing proteinuria and retarding the rate of renal progression remain to be determined. Prophylactic antibiotics and tonsillectomy may reduce the frequency of gross hematuria but have no proven benefit on reducing the rate of renal disease progression. Patients with IgA nephropathy may undergo successful renal transplantation. Although recurrent disease is frequent, allograft loss caused by IgA nephropathy occurs in only 15–30% of patients.

502.2 Alport Syndrome

Alport syndrome (AS), hereditary nephritis, is a genetically heterogeneous disease caused by mutations in the genes coding for type IV collagen, a major component of basement membranes. These genetic alterations are associated with marked variability in clinical presentation, natural history, and histologic abnormalities.

Genetics.

Approximately 85% of patients have X- linked disease caused by a mutation in the *COL4A5* gene encoding the a5 chain of type IV collagen. Patients with a subtype of X-linked AS and diffuse leiomyomatosis demonstrate a contiguous mutation within the *COL4A5* and *COL4A6* genes that encodes the a5 and

a6 chains, respectively, of type IV collagen. Autosomal recessive forms of AS are caused by mutations in the *COL4A3* and *COL4A4* genes on chromosome 2 encoding the a3 and a4 chains, respectively, of type IV collagen. An autosomal dominant form of AS linked to the *COL4A3-COL4A4* gene locus occurs in 5% of cases.

Pathology.

Kidney biopsy specimens during the first decade of life may show few changes on light microscopy. Later, the glomeruli may develop mesangial proliferation and capillary wall thickening, leading to progressive glomerular sclerosis. Tubular atrophy, interstitial inflammation and fibrosis, and presence of lipid containing tubular or interstitial cells, referred to as foam cells, develop as the disease progresses. Immunopathologic studies are usually nondiagnostic.

In most patients, electron microscopic studies reveal diffuse thickening, thinning, splitting, and layering of the basement membranes of the glomeruli (Fig. 502–3) and tubules. However, ultrastructural analysis of the GBM may be completely normal, display nonspecific alterations, or demonstrate only uniform thinning in families that have the typical clinical manifestations of AS.

Clinical Manifestations.

All patients with Alport syndrome have asymptomatic microscopic hematuria, which may be intermittent in girls and younger boys. Single or recurrent episodes of gross hematuria commonly occurring 1–2 days after an upper respiratory infection are seen in approximately 50% of patients. Proteinuria is frequently seen in males but may be absent, mild, or intermittent in females. Progressive proteinuria, often exceeding 1?g/24?hr, is common by the second decade of life and can be severe enough to cause nephrotic syndrome.

Extrarenal manifestations of AS include hearing deficits and ocular abnormalities. Bilateral sensorineural hearing loss, which is never congenital in onset, occurs in 90% of hemizygous males with X-linked AS, 10% of heterozygous females with X-linked AS, and 67% of individuals with autosomal recessive AS. This deficit begins in the high-frequency range but progresses to involve conversational speech, prompting the need for hearing aids. Ocular abnormalities, which occur in 30–40% of patients with X-linked AS, include anterior lenticonus (extrusion of the central portion of the lens into the anterior chamber), macular flecks, and corneal erosions. Leiomyomatosis of the esophagus, tracheobronchial tree, and female genitals and platelet abnormalities are rarely seen.

Diagnosis.

A careful family history, a screening urinalysis of first-degree relatives, an audiogram, and an ophthalmologic

Figure 502.2-3 Electron micrograph of the biopsy specimen from a child with Alport syndrome depicting thickening, thinning, splitting, and layering of the glomerular basement membrane. (×16,250.) (From Yum M, Bergstein JM: Basement membrane nephropathy. *Hum Pathol* 14:996, 1983.)

examination are critical in making the diagnosis of AS. Presence of anterior lenticonus is pathognomonic. AS is highly likely in the patient with hematuria and at least two of the following characteristic clinical features: macular flecks, recurrent corneal erosions, GBM thickening and thinning, and sensorineural deafness. Absence of epidermal basement membrane staining for the a5 chain of type IV collagen in male hemizygotes and discontinuous epidermal basement membrane staining in female heterozygotes is pathognomonic for _X-linked AS. Mutation screening or linkage analysis is not readily available for routine clinical use. Prenatal diagnosis is available for families with X-linked AS individuals who carry an identified mutation.

Prognosis and Treatment.

The risk of progressive renal dysfunction leading to end-stage renal disease (ESRD) is highest among hemizygotes and autosomal recessive homozygotes. ESRD occurs before age 30 yr in approximately 75% of hemizygotes with X-linked AS. The risk of ESRD in X-linked heterozygotes is 12% by age 40 and 30% by age 60. Risk factors for progression are gross hematuria during childhood, nephrotic syndrome, and prominent GBM thickening. Intrafamilial variation in phenotypic expression results in significant differences in the age of ESRD among family members. No specific therapy is available to treat AS, although some studies suggest that cyclosporine and angiotensin-converting enzyme inhibitors may slow the rate of renal progression. Careful management of renal failure complications such as hypertension, anemia, and electrolyte imbalance is critical. Patients with ESRD are treated with dialysis and successful kidney transplantation. Approximately 5% of renal transplant recipients develop anti-GBM nephritis, which occurs primarily in males with X-linked AS who develop ESRD before age 30 yr.

502.3 Thin Glomerular Basement Membrane Disease

Thin glomerular basement membrane disease (TGBMD) is defined by the presence of persistent microscopic hematuria and isolated thinning of the GBM on electron microscopy. Isolated hematuria in multiple family members without renal dysfunction is referred to as *benign familial hematuria*.

TGBMD may be sporadic or transmitted as an autosomal dominant trait. Mutations in the *COL4A3* and *COL4A4* genes among heterozygotes with benign familial hematuria have been reported. However, family kindreds with isolated GBM thinning

and no identified mutations within the type IV collagen genes have also been reported.

Microscopic hematuria is usually persistent and often initially observed during childhood. However, hematuria may initially present in adulthood and may be intermittent. Episodic gross hematuria may also be present, particularly after a respiratory illness. There is no treatment. Progressive renal insufficiency, hypertension, proteinuria, and extrarenal manifestations of TGBMD are rare and suggest the presence of AS. GBM thinning may also be seen in IgA nephropathy.

Chapter 503 - Glomerulonephritis Associated with Infections

503.1 Acute Poststreptococcal Glomerulonephritis

This disease is a classic example of the acute nephritic syndrome characterized by the sudden onset of gross hematuria, edema, hypertension, and renal insufficiency. Acute poststreptococcal glomerulonephritis is one of the most common glomerular causes of gross hematuria in children, surpassed only by IgA nephropathy.

Etiology and Epidemiology.

Acute poststreptococcal glomerulonephritis follows infection of the throat or skin by certain “nephritogenic” strains of group A ß-hemolytic streptococci. The factors that allow only certain strains of streptococci to be nephritogenic remain unclear. Poststreptococcal glomerulonephritis commonly follows streptococcal pharyngitis during cold weather months and streptococcal skin infections or pyoderma during warm weather months. Although epidemics of nephritis have been described in association with both throat (serotype 12) and skin (serotype 49) infections, this disease is most commonly sporadic.

Pathology.

As in most forms of acute glomerulonephritis, the kidneys appear symmetrically enlarged. On light microscopy, all glomeruli appear enlarged and relatively bloodless and show diffuse mesangial cell proliferation with an increase in mesangial matrix (Fig. 503–1). Polymorphonuclear leukocytes are common in glomeruli during the early stage of the disease. Crescents and interstitial inflammation may be seen in severe cases. These changes are not specific for poststreptococcal glomerulonephritis. Immunofluorescence microscopy reveals lumpy-bumpy deposits of immunoglobulin and complement on the glomerular basement membrane (GBM) and in the mesangium. On electron microscopy, electron-dense deposits, or “humps,” are observed on the epithelial side of the GBM (Fig. 503–2).

Pathogenesis.

Although morphologic studies and a depression in the serum complement (C3) level

strongly suggest that post-streptococcal

Figure 503.1-1 Glomerulus from a patient having poststreptococcal glomerulonephritis appearing enlarged and relatively bloodless and showing mesangial proliferation and exudation of neutrophils. (×400.)

Figure 503.1-2 Electron micrograph in poststreptococcal glomerulonephritis demonstrating electron-dense deposits (D) on the epithelial cell (Ep) side of the glomerular basement membrane. A polymorphonuclear leukocyte (P) is present within the lumen (L) of the capillary. BS = Bowman space; M = mesangium.

glomerulonephritis is mediated by immune complexes, the precise mechanisms by which nephritogenic streptococci induce complex formation remain to be determined. Despite clinical and histologic similarities to acute serum sickness in rabbits, the finding of circulating immune complexes in poststreptococcal glomerulonephritis is not uniform and complement activation is primarily through the alternative rather than the classic (immune complex activated) pathway.

Clinical Manifestations.

Poststreptococcal glomerulonephritis is most common in children aged 5–12 yr and uncommon before the age of 3 yr. The typical patient develops an acute nephritic syndrome 1–2 wk after an antecedent streptococcal pharyngitis or 3–6 wk after a streptococcal pyoderma. The severity of renal involvement varies from asymptomatic microscopic hematuria with normal renal function to acute renal failure. Depending on the severity of renal involvement, patients may develop various degrees of edema, hypertension, and oliguria. Patients may develop encephalopathy and/or heart failure owing to hypertension or hypervolemia. Encephalopathy may also result directly from the toxic effects of the streptococcal bacteria on the central nervous system. Edema typically results from salt and water retention and nephrotic syndrome may develop in 10–20% of cases. Specific symptoms such as malaise, lethargy, abdominal or flank pain, and fever are common. Acute subglottic edema and airway compromise has also been reported. The acute phase generally resolves within 6–8 wk. Although urinary protein excretion and hypertension usually normalize by 4–6 wk after onset, persistent microscopic hematuria may persist for 1–2 yr after the initial presentation.

Diagnosis.

Urinalysis demonstrates red blood cells (RBCs), frequently in association with RBC casts, proteinuria, and polymorphonuclear leukocytes. A mild normochromic anemia may be present from hemodilution and low-grade hemolysis. The serum C3 level is usually reduced in the acute phase and returns to normal 6–8 wk after onset.

Confirmation of the diagnosis requires clear evidence of invasive streptococcal infection. A positive throat culture report may support the diagnosis or may simply represent the carrier state. On the other hand, a rising antibody titer to streptococcal antigen(s) confirms a recent streptococcal infection. Importantly, the antistreptolysin O titer is commonly elevated after a pharyngeal infection but rarely increases after streptococcal skin infections. The best single antibody titer to document cutaneous streptococcal infection is the deoxyribonuclease (DNase) B antigen. The Streptozyme test (Wampole Laboratories, Stamford, CT) is an alternative study that detects antibodies to streptolysin O, DNase B, hyaluronidase, streptokinase, and nicotinamide-adenine dinucleotidase using a slide agglutination test.

The clinical diagnosis of poststreptococcal glomerulonephritis is quite likely in a child presenting with acute nephritic syndrome, evidence of recent streptococcal infection, and a low C3 level. However, it is important to consider other diagnoses such as systemic lupus erythematosus and an acute exacerbation of chronic glomerulonephritis. Renal biopsy should be considered only in the presence of acute renal failure, nephrotic syndrome, absence of evidence for streptococcal infection, or normal complement levels. Also, renal biopsy is considered when hematuria and proteinuria, diminished renal function, and/or a low C3 level persist more than 2 mo after onset.

The differential diagnosis of poststreptococcal glomerulonephritis includes many of the causes of hematuria listed in Box 501–2 . Acute glomerulonephritis may also follow infection with coagulase-positive and coagulase-negative staphylococci, *Streptococcus pneumoniae*, and gram-negative bacteria. Also, bacterial endocarditis may produce a hypocomplemententemic glomerulonephritis with renal failure. Finally, acute glomerulonephritis may occur after certain fungal, rickettsial, and viral diseases, particularly, influenza.

Complications.

Acute complications of this disease result primarily from hypertension and acute renal dysfunction. Hypertension is seen in 60% of patients and may be associated with hypertensive encephalopathy in 10% of cases. Other potential complications include heart failure, hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, seizures, and uremia.

Prevention.

Early systemic antibiotic therapy for streptococcal throat and skin infections does not eliminate the risk of glomerulonephritis. Family members of patients with acute glomerulonephritis should be cultured for group A ß-hemolytic streptococci and treated if culture positive.

Treatment.

Management is directed at treating the acute effects of renal insufficiency and hypertension (see Chapter 527.1). Although a 10-day course of systemic antibiotic therapy with penicillin is recommended to limit the spread of the nephritogenic organisms, antibiotic therapy does not affect the natural history of glomerulonephritis. Sodium restriction, diuresis, and pharmacotherapy with calcium channel antagonists, vasodilators, or angiotensin-converting enzyme inhibitors are

standard therapies used to treat hypertension.

Prognosis.

Complete recovery occurs in more than 95% of children with acute poststreptococcal glomerulonephritis. Mortality in the acute stage can be avoided by appropriate management of acute renal failure, cardiac failure, and hypertension. Infrequently, the acute phase may be severe and lead to glomerular hyalinization and chronic renal insufficiency. However, the diagnosis of acute poststreptococcal glomerulonephritis must be questioned in patients with chronic renal dysfunction because other diagnoses such as membranoproliferative glomerulonephritis may be present. Recurrences are extremely rare.

503.2 Other Chronic Infections

Occurrence of glomerulonephritis has been recognized during the course of various chronic infections, including bacterial endocarditis caused by *Streptococcus viridans* and other organisms, ventriculoatrial shunts for hydrocephalus infected with *Staphylococcus epidermidis*, syphilis, hepatitis B virus, hepatitis C virus, and candidiasis. Parasitic infections associated with glomerular disease include malaria, schistosomiasis, leishmaniasis, filariasis, hydatid disease, trypanosomiasis, and toxoplasmosis. In each condition, the infecting organism has low virulence and the host is chronically infected with foreign antigen. In the presence of high levels of circulating antigen, the host's antibody response leads to formation of immune complexes that deposit in the kidneys and initiate glomerular inflammation.

The histopathologic findings may resemble poststreptococcal, membranous, or membranoproliferative glomerulonephritis. The clinical manifestations are generally those of an acute nephritic or nephrotic syndrome. The complement C3 level is frequently depressed.

Eradication of the infection before severe glomerular injury occurs usually results in resolution of the glomerulonephritis. Progression to end-stage renal failure has been described.

Chapter 504 - Membranous Glomerulopathy (Glomerulonephritis)

Although membranous glomerulopathy is the most common cause of nephrotic syndrome in adults, it is an uncommon cause of hematuria in children. Membranous glomerulopathy typically presents as an isolated renal disease. However, it may be associated with systemic illnesses, including autoimmune diseases such as systemic lupus erythematosus or chronic immune thrombocytopenic purpura, sarcoidosis, neuroblastoma, gonadoblastoma, gold or penicillamine therapy, syphilis,

and hepatitis B virus infections. These secondary causes of membranous glomerulopathy are more common in children compared to adults. Furthermore, identification of these secondary causes of membranous glomerulopathy is important because treatment of these diseases may lead to resolution of the glomerular lesions.

Pathology.

By light microscopy, the glomeruli show diffuse thickening of the glomerular basement membrane (GBM), without significant proliferative changes (Fig. 504–1). The thickening presumably results from the production of membrane-like material by the visceral epithelial cells in response to immune complexes deposited on the epithelial side of the membrane. This new material may in certain areas resemble spikes on the epithelial side of the GBM. Immunofluorescent microscopy demonstrates granular deposits of IgG and C3 located on the epithelial side of the GBM when viewed under electron microscopy. Linear staining of IgG, IgA, and C3 along the tubular basement membrane may be seen on immunofluorescence.

Pathogenesis.

Morphologic studies suggest that membranous glomerulopathy is an immune complex–mediated disease. However, the molecular pathogenesis of membranous nephropathy in humans remains unknown. Genetic factors may influence disease susceptibility and/or disease progression.

Clinical Manifestations.

In children, membranous glomerulopathy is most common in the 2nd decade of life. The disease usually presents as nephrotic syndrome and accounts for 2–6% of childhood nephrotic syndrome cases. Most patients have microscopic hematuria and occasionally gross hematuria. Approximately 20% of children present with hypertension. C3 levels are normal except in cases of systemic lupus erythematosus in which levels may be depressed.

Diagnosis.

The diagnosis of membranous nephropathy is confirmed only by kidney biopsy because no single laboratory test is diagnostic. The usual indications for biopsy include the presentation of nephrotic syndrome in a child, usually older than 10 yr, or the presence of unexplained hematuria and proteinuria. Patients with membranous glomerulopathy are at an increased risk for renal vein thrombosis.

Prognosis and Treatment.

The clinical course of membranous glomerulopathy is variable, although children presenting with asymptomatic low-grade proteinuria may achieve a spontaneous remission. Follow-up studies of 1–14 yr suggest that 20% of children progress to chronic renal failure whereas 40% continue with active disease. The nephrotic state is best controlled

Figure 504-1 Glomerulus from a patient having membranous glomerulopathy, demonstrating diffuse thickening of the glomerular basement membrane in the absence of cellular proliferation. (×400.)

with salt restriction and diuretic agents. Studies in adults suggest that immunosuppressive therapy with prednisone in conjunction with chlorambucil or cyclophosphamide may be beneficial in slowing the rate of progressive renal disease, particularly in patients with severe or prolonged proteinuria, renal insufficiency, or hypertension. **REFERENCES**

Chapter 505 - Membranoproliferative (Mesangiocapillary) Glomerulonephritis

The term *chronic glomerulonephritis* implies continuing glomerular injury that frequently leads to glomerular destruction and end-stage renal failure. Membranoproliferative glomerulonephritis (MPGN) is the most common cause of chronic glomerulonephritis in older children and young adults.

Pathology and Pathogenesis.

MPGN was initially distinguished from other forms of chronic glomerulonephritis by the finding of hypocomplementemia in most patients. In some patients, hypocomplementemia results from an antibody, referred to as C3 nephritic factor, that activates the alternative complement pathway. Three histologic types of MPGN are described.

Type I MPGN is the most common form. The glomeruli reveal an accentuation of the lobular pattern, owing to a generalized increase in mesangial cells and matrix (Fig. 505–1). The glomerular capillary walls appear thickened, often containing regions of duplication or splitting from interposition of mesangial cytoplasm and matrix between the endothelial cells and

Figure 505-1 Glomerulus from a patient with type I membranoproliferative glomerulonephritis demonstrating an accentuated lobular pattern, a generalized increase in mesangial cells and matrix, and “splitting” of the glomerular capillary wall *(inset).* (×250.) (From Kim Y, Michael AF: Idiopathic membranoproliferative glomerulonephritis. Reproduced with permission from the *Annual Review of Medicine,* vol 31. © 1980 by Annual Reviews, Inc.)

glomerular basement membrane (GBM). Crescents may be present and indicate a poor prognosis when detected in a high percentage of glomeruli. Immunofluorescent microscopy reveals C3 and lesser amounts of immunoglobulin in the mesangium and along the peripheral capillary walls in a lobular pattern (Fig. 505–2). Electron microscopy confirms the presence of immune complex–like deposits in the mesangial and subendothelial regions.

In *type II disease*, the mesangial changes are less prominent than in type I. The capillary walls demonstrate irregular ribbon-like thickening owing to the deposition of

electron-dense deposits. Splitting of the membrane is rare, but crescents are common. On electron microscopy, the dense deposits are seen as thickenings of GBM in a region distinct from the lamina densa. The deposits are also found in Bowman capsule, mesangium, and tubular basement membranes. Immunofluorescent studies show C3 and minimal immunoglobulin along the margin of the dense deposit material.

In *type III disease*, the light and immunofluorescent microscopic findings resemble those found in type I disease. Electron microscopy reveals contiguous subepithelial and subendothelial deposits associated with disruption and layering of the lamina densa portion of the GBM.

Clinical Manifestations.

MPGN is most common in the second decade of life. The majority of patients present with nephrotic syndrome, although others may present with acute nephritic syndrome characterized by gross hematuria or asymptomatic microscopic hematuria and proteinuria. Renal function may be normal or depressed. Hypertension is common. The serum C3 complement level may be decreased.

Diagnosis and Differential Diagnosis.

The diagnosis of MPGN is made by renal biopsy. Indications for biopsy include nephrotic syndrome in a child older than 10 yr, significant proteinuria with microscopic hematuria, or hypocomplementemia greater than 8 wk duration in a child with acute nephritis.

Both MPGN and poststreptococcal glomerulonephritis may be associated with gross hematuria, low C3 levels, and elevated antistreptococcal antibody titers. However, patients with poststreptococcal glomerulonephritis improve dramatically within 2 mo of onset whereas nephritic syndrome, proteinuria, and hypocomplementemia persist in children with MPGN, resulting in the need for a kidney biopsy.

Figure 505-2 Immunofluorescence microscopy in type I membranoproliferative glomerulonephritis, demonstrating granular deposition of C3 along the glomerular basement membranes and in the mesangium. (×610.) (From Kim Y, Michael AF: Idiopathic membranoproliferative glomerulonephritis. Reproduced with permission from the *Annual Review of Medicine,* vol 31. © 1980 by Annual Reviews, Inc.)

Prognosis and Treatment.

Although some patients recover completely, approximately 50% of patients with MPGN progress to end-stage renal disease 10 yr after their initial presentation. Prognosis appears to be affected by histologic type because patients with type II MPGN have a worse prognosis compared with those with types I and III. Recurrence of MPGN in the kidney transplant occurs in approximately 30% of patients with type I and close to 90% of patients with type II, suggesting the presence of a systemic disorder. No definitive therapy exists, although stabilization of the clinical course has been reported in many patients receiving long-term alternate-day prednisone therapy.

Chapter 506 - Glomerulonephritis Associated with Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is characterized by fever, weight loss, rash, hematologic abnormalities, arthritis, and involvement of the heart, lungs, central nervous system, and kidneys. The nonrenal manifestations are discussed in Chapter 148 . Kidney disease, one of the most common manifestations of SLE in childhood, may occasionally be the only manifestation.

Pathogenesis and Pathology.

Studies in a mouse strain and in humans suggest that the clinical manifestations of SLE are mediated by immune complexes. Aberrations in both B-cell and T-cell function are noted.

The classification of lupus nephritis of the World Health Organization (WHO) is based on light microscopy, immunofluorescence, and electron microscopy. In patients with WHO class I nephritis, no histologic abnormalities are detected. In WHO class II nephritis (mesangial lupus nephritis), glomeruli demonstrate mesangial deposits containing immunoglobulin and complement; light microscopy may show mild (class II-A) or moderate mesangial hypercellularity and increased matrix (class II-B).

In WHO class III nephritis (focal segmental lupus glomerulonephritis), mesangial deposits occur in almost all glomeruli and subendothelial deposits are noted between the endothelial cells and glomerular basement membrane. In addition to focal and segmental mesangial proliferation, occasional glomeruli show capillary wall necrosis, crescent formation, and sclerosis lesions.

WHO class IV nephritis (diffuse proliferative lupus nephritis) is the most common and most severe form of lupus nephritis. All glomeruli contain massive mesangial and subendothelial deposits of immunoglobulin and complement. On light microscopy, all glomeruli show mesangial proliferation. The capillary walls are frequently thickened owing to subendothelial deposits creating the wire-loop lesion and often demonstrate necrosis, crescent formation, and scarring.

WHO class V nephritis (membranous lupus nephritis) is the least common form. It resembles idiopathic membranous glomerulopathy histologically, except for mild to moderate mesangial proliferation.

Transformation of the histologic lesion from one class to another is common. This is more likely to occur among inadequately treated patients and usually results in progression to a more severe histologic lesion.

Clinical Manifestations.

The majority of children with SLE are adolescent females. Clinical evidence of renal disease occurs in 30–70% of children. The clinical findings in patients having the milder forms (all class II, some class III) of lupus nephritis include hematuria, normal renal function, and proteinuria of less than 1?g/24?hr. Some patients with class III and all patients with class IV nephritis have hematuria and proteinuria, reduced renal function, nephrotic syndrome, or acute renal failure. In rare patients with proliferative glomerulonephritis, the urinalysis may be completely normal. Patients with class V nephritis commonly present with nephrotic syndrome.

Diagnosis.

The diagnosis of SLE is suggested by the detection of circulating antinuclear antibodies and is confirmed by demonstrating antibodies that react with native double-stranded DNA. In most patients with active disease, C3 and C4 levels are depressed. In view of the lack of clear correlation between the clinical manifestations and the severity of the renal involvement, renal biopsy should be performed in all patients with SLE. These results are used to guide the selection of immunosuppressive therapies.

Treatment.

Patients with SLE should be treated by specialists in medical centers where both medical and psychologic support can be given to both patients and their families. Immunosuppressive therapy in lupus nephritis is aimed at establishing a clinical and serologic remission as defined by normalization of anti-DNA, C3, and C4 levels. Therapy is initiated in all patients with prednisone at a dose of 1–2?mg/kg/day divided into two or three doses followed by a slow steroid taper over 4–6 mo beginning 4–6 wk after achieving a serologic remission. For patients having more severe forms of nephritis (WHO class III and class IV), six monthly intravenous infusions of cyclophosphamide at a dose of 500–1000?mg/m^2 followed by every-3-month dosing for 18–36 months appears to reduce the risk of progressive renal dysfunction. Azathioprine at a single daily dose of 1.5–2.0?mg/kg may be used as a steroid-sparing agent in patients with WHO class I or II lupus nephritis. Single center case reports also suggest the potential benefit of mycophenolate mofetil in patients with mild lupus nephritis.

Prognosis.

Aggressive immunosuppressive therapy has dramatically improved the prognosis of SLE in childhood. Renal survival without the need for dialysis is seen in 80% of patients 10 yr after the diagnosis of SLE nephritis. Patients with diffuse proliferative

WHO class IV lupus nephritis exhibit the highest risk for progression to end-stage renal disease. Concerns regarding the side effects of chronic immunosuppressive therapy and the risk of recurrent disease are lifelong. Special care must be taken to minimize the risks of osteoporosis, obesity, hypertension, and diabetes mellitus associated with chronic steroid therapy. The risk for malignancy or infertility is increased in patients receiving a cumulative dose of more than 20?g of cyclophosphamide.

Chapter 507 - Henoch-Schönlein Purpura Nephritis

Henoch-Schönlein purpura (HSP) nephritis, also referred to as anaphylactoid purpura, is a small vessel vasculitis characterized by a purpuric rash, arthritis, abdominal pain, and glomerulonephritis (see Chapter 157.1). HSP nephritis and IgA nephropathy demonstrate identical renal findings, but systemic findings are only seen in HSP nephritis.

Pathology and Pathogenesis.

Glomerular and tubulointerstitial abnormalities on light, immunofluorescence, and electron microscopy in HSP nephritis are virtually indistinguishable from the pathologic findings in IgA nephropathy. However, crescent formation is more common and more extensive in patients with HSP nephritis. Although the pathogenesis of HSP nephritis remains unknown, this disease appears to be mediated by the formation of immune complexes containing polymeric IgA1 within capillaries of the skin, intestines, and glomerulus.

Clinical and Laboratory Manifestations.

The symptoms and signs of HSP nephritis typically appear 1–3 wk after an upper respiratory tract infection (see Chapter 157.1). The diagnosis of HSP is based on the constellation of clinical findings. Whereas gross hematuria is seen in 20–30% of cases, patients may also present with isolated microscopic hematuria, hematuria and proteinuria, acute nephritic syndrome, nephrotic syndrome, or renal insufficiency. Renal manifestations of HSP nephritis occur up to 12 wk after the initial presentation of HSP. An uncommon urologic manifestation of this disease is ureteritis, which is associated with loin pain and renal colic. Ureteritis is usually seen in children younger than 5 yr of age and frequently leads to ureteral stenosis and hydronephrosis requiring surgical correction.

Prognosis and Treatment.

The prognosis in HSP nephritis is generally favorable, although the risk of chronic renal insufficiency is 2–5%. Presentation with isolated microscopic hematuria alone carries the best prognosis whereas presentation with acute nephritic syndrome and nephrotic syndrome carries the highest risk of developing chronic renal failure.

There are no controlled data demonstrating that steroids, cytotoxic agents, or anticoagulants alter the course of HSP nephritis. However, uncontrolled studies suggest the potential value of high doses of steroids and cytotoxic therapy with

cyclophosphamide or azathioprine in patients with crescentic glomerulonephritis or significant proteinuria. Addition of dipyridamole and/or heparin/warfarin may provide additional benefit in these severe forms of nephritis. Although some studies suggest that short courses of low-dose prednisone reduce the risk of developing any clinical signs of nephritis, it is unclear whether this therapy reduces the risk for progression to severe renal disease. Tonsillectomy does not appear to alter the course of HSP nephritis.

Chapter 508 - Rapidly Progressive (Crescentic) Glomerulonephritis

“Rapidly progressive” describes the clinical course of several forms of glomerulonephritis (GN) whose unifying abnormality is the presence of crescents in the majority of glomeruli. The natural history in most forms is rapid progression to end-stage renal failure.

Classification.

Crescents may be found in several well-defined types of glomerulonephritis, including (1) immune-complex– mediated forms of GN: poststreptococcal GN, lupus nephritis, membranoproliferative GN, and Henoch-Schönlein purpura/ IgA nephritis; (2) anti–glomerular basement membrane–mediated GN, such as Goodpasture disease; and (3) anti–neutrophil cytoplasmic antibody (ANCA)–mediated GN: microscopic polyarteritis nodosa and Wegener granulomatosis. The typical findings on light, immunofluorescent, and electron microscopic examinations are maintained despite crescent formation. These histologic findings, in conjunction with clinical features and appropriate laboratory studies, should reveal the underlying disease. If recognized forms of glomerulonephritis are excluded, the category of idiopathic rapidly progressive disease remains.

Pathology and Pathogenesis.

Crescents are found on the inside of Bowman capsule and are composed of proliferating epithelial cells of the capsule, fibrin, basement membrane–like material, and macrophages (Fig. 508–1). The stimulus for crescent formation is presumed to be the deposition of fibrin in Bowman space, probably as a result of necrosis or disruption of the glomerular capillary wall. Many patients display capillary wall immune-complex deposits or linear IgG antibody staining against glomerular basement membrane. Immunofluorescence and electron microscopy studies in patients with ANCA-mediated forms of GN typically show no evidence of immunologic injury. The complement C3 level is normal.

Clinical Manifestations.

Most patients develop acute renal failure associated with acute nephritic and/or nephrotic syndrome. Progression to end-stage renal failure usually occurs within

weeks to months after onset.

Diagnosis and Differential Diagnosis.

Appropriate serologic studies such as antinuclear antibody, C3, and anti-deoxyribonucleotidase

Figure 508-1 Light micrograph of a biopsy specimen from a child with Henoch-Schönlein purpura glomerulonephritis demonstrating a crescent overlying the glomerulus. (×180.)

B titers should be obtained to delineate specific types of glomerulonephritis. Rare forms of vasculitis, such as Wegener granulomatosis and microscopic polyarteritis nodosa, may be suggested by the detection of ANCA antibodies to either myeloperoxidase or serine proteinase-3 (PR-3) within the neutrophil cytoplasm. The diagnosis is confirmed by kidney biopsy.

Prognosis and Treatment.

Children with a rapidly progressive course associated with poststreptococcal glomerulonephritis usually recover spontaneously. Excellent therapeutic response using a combination of steroids and cytotoxic therapy with cyclophosphamide often occurs in patients with systemic lupus erythematosus, IgA nephropathy, and Henoch-Schönlein purpura nephritis. Renal outcomes in other diseases causing rapidly progressive glomerulonephritis are less favorable, with end-stage renal disease occurring within 2–3 yr. However, therapy combining pulse methylprednisolone and oral cyclophosphamide may be effective, particularly in patients with Wegener granulomatosis. Plasmapheresis or lymphocytapheresis has been reported to be effective in individual cases.

Chapter 509 - Goodpasture Disease

Goodpasture disease is characterized by pulmonary hemorrhage and glomerulonephritis associated with antibodies commonly directed against specific epitopes of type IV collagen within the alveolar basement membrane of the lung and glomerular basement membrane (GBM) of the glomerulus. The etiology of these antibodies is unknown. This entity should be distinguished from Goodpasture syndrome, which is a clinical picture of pulmonary hemorrhage and glomerulonephritis that may be seen with several disorders, including systemic lupus erythematosus, Henoch-Schönlein purpura, polyarteritis nodosa, and Wegener granulomatosis. In some patients, anti-GBM nephritis occurs without pulmonary hemorrhage as one form of rapidly progressive glomerulonephritis.

Pathology.

In most patients, the changes on light microscopy resemble those of rapidly progressive glomerulonephritis. Immunofluorescent microscopy demonstrates a continuous linear pattern of IgG along the GBM (Fig. 509–1).

Clinical Manifestations.

Goodpasture disease is rare in childhood. Patients usually present with hemoptysis that is associated with pulmonary hemorrhage that can be life threatening. Renal manifestations include acute nephritic syndrome with hematuria, proteinuria, and hypertension. Progressive renal dysfunction occurs within days to weeks. The complement C3 level is normal.

Diagnosis.

The diagnosis is suggested by kidney biopsy. Serum antibodies to the GBM confirm the diagnosis and rule out other disorders associated with Goodpasture syndrome.

Figure 509-1 Immunofluorescence micrograph demonstrating the continuous linear staining of IgG along the glomerular basement membrane, as found in diseases mediated by anti– glomerular basement membrane antibody. (×250.)

Prognosis and Treatment.

Patients who survive the pulmonary hemorrhage commonly progress to end-stage renal failure. Rates of survival and recovery of renal function have improved with pulse methylprednisolone, oral cyclophosphamide, and plasmapheresis therapy.

Chapter 510 - Hemolytic-Uremic Syndrome

The hemolytic-uremic syndrome (HUS) is the most common cause of acute renal failure in young children and is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and uremia. HUS has features common to thrombotic thrombocytopenic purpura, except that the latter tends to occur in young adult women as a relapsing illness with fever, serious central nervous system involvement, and thrombocytopenia.

Etiology.

An acute enteritis with diarrhea caused by Shiga toxin–producing *Escherichia coli* 0157:H7 precedes 80% or more of HUS cases in developed countries. The reservoir of this organism is the intestinal tract of domestic animals. It is usually transmitted by undercooked meat and unpasteurized milk. Outbreaks have followed ingestion of contaminated apple cider or bathing in a contaminated swimming pool. The organism elaborates a toxin, verotoxin, which is absorbed from the intestines and initiates endothelial cell injury. Less often, HUS is associated with other bacterial *(Shigella, Salmonella, Campylobacter, Streptococcus pneumoniae, Bartonella)* and viral (coxsackievirus, echovirus, influenza, varicella, HIV, Epstein-Barr) infections. HUS may also develop with the use of oral contraceptives, mitomycin, cyclosporine, and pyran copolymer, which is an inducer of interferon. In addition, a hemolytic-uremic type of disorder has been reported with systemic lupus erythematosus, malignant hypertension, preeclampsia, postpartum renal failure, and radiation nephritis. Several reports describe occurrence in more than one member of a family, but the role of genetic factors in predisposition to the disease is unknown.

Pathology.

Initial glomerular changes include thickening of the capillary walls, narrowing of the capillary lumens, and widening of the mesangium. Electron microscopy shows these changes to be the result of subendothelial and mesangial deposition of a granular, amorphous material of unknown origin. Fibrin thrombi can be found in glomerular capillaries and arterioles and may lead to cortical necrosis.

Severely involved glomeruli progress to partial or total sclerosis. Severe vascular involvement may render other glomeruli obsolescent as a result of ischemia. In these severely involved small arteries and arterioles, concentric intimal proliferation leads to vascular occlusion.

Pathogenesis.

The primary event in pathogenesis of the syndrome appears to be endothelial cell injury. Capillary and arteriolar endothelial injury in the kidney leads to localized clotting. Evidence for disseminated intravascular coagulation is unusual. The microangiopathic anemia results from mechanical damage to the red blood cells (RBCs) as they pass through the altered vasculature. Thrombocytopenia is caused by intrarenal platelet adhesion or damage. Damaged RBCs and platelets are removed from circulation by the liver and spleen. Nondiarrheal and sporadic familial cases of HUS may be caused by the absence of a plasma factor that stimulates the production of endothelial cell–derived prostacyclin, which promotes vasodilatation and inhibits thrombosis. Reduced levels of thrombomodulin, tissue plasminogen activator, and heparin-like molecules, which activate antithrombin III, result in a prothrombotic state in HUS. In addition, serum levels of prothrombotic agents, including platelet- activating factor, prothrombin fragment 1 and 2, tissue plasminogen activator antigen, tissue plasminogen activator-inhibitor (TPA-1) complex, von Willebrand factor, D-dimer, and thromboxane A_2 are increased before renal injury occurs and may be a cause of injury.

Clinical Manifestations.

HUS is most common in children younger than age 4 yr. The onset is usually preceded by a gastroenteritis characterized by fever, vomiting, abdominal pain, and diarrhea that is often bloody. Less commonly, patients may present after an upper respiratory tract infection. Sudden onset of pallor, irritability, weakness, lethargy, and oliguria usually occurs 5–10 days after the initial gastrointestinal or respiratory illness. Physical examination may reveal dehydration, edema, petechiae, hepatosplenomegaly, and marked irritability.

Diagnosis and Differential Diagnosis.

The diagnosis is supported by the findings of a microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. The hemoglobin value is commonly in the range of 5–9?g/dL. The blood peripheral smear reveals helmet cells, burr cells, and fragmented RBCs (see Chapter 439). Plasma hemoglobin levels are elevated, whereas plasma haptoglobin levels are diminished. The reticulocyte count is moderately elevated, and the Coombs test result is negative. The leukocyte count may increase to 30,000/mm^3 . Thrombocytopenia (20,000–100,000/mm^3) occurs in more than 90% of patients. Findings on urinalysis are surprisingly mild and usually consist of low-grade microscopic hematuria and proteinuria. Partial thromboplastin time and prothrombin time are usually normal. Prolongation of coagulation studies is more commonly caused by vitamin K deficiency than by disseminated intravascular coagulation. Renal manifestations vary from mild renal insufficiency to acute renal failure requiring dialysis. Barium contrast studies reveal colonic spasm and transient early filling defects. Intestinal strictures are rare sequelae.

HUS should always be considered in the child with a sudden onset of acute renal failure. The typical history, clinical picture, and laboratory findings confirm the diagnosis in most patients.

Other causes of acute renal failure, especially those that can be associated with a microangiopathic hemolytic anemia such as systemic lupus erythematosus and malignant hypertension, should be excluded. A renal biopsy is rarely indicated.

Patients with bilateral renal vein thrombosis (see Chapter 511.7) may be difficult to distinguish from those with HUS. Both disorders may be preceded by a gastrointestinal disorder associated with dehydration, pallor, and evidence of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. Marked renal enlargement and absence of renal vein flow by renal Doppler ultrasonography is consistent with renal vein thrombosis.

Complications.

Complications include anemia, acidosis, hyperkalemia, fluid overload, heart failure, hypertension, and uremia. Extrarenal manifestations of the central nervous system, gastrointestinal tract, heart, and skeletal muscles may be life threatening. Central nervous system dysfunction includes irritability, seizures, infarcts of the basal ganglion and cerebral cortex, cortical blindness, and coma. Gastrointestinal manifestations include colitis, intestinal perforation, intussusception, and hepatitis. Focal pancreatic necrosis may result in glucose intolerance, insulin-dependent diabetes mellitus, and elevated lipase levels. Pericarditis, myocardial dysfunction, and arrhythmias may be seen in cases with cardiac involvement. Other complications such as skin necrosis, parotitis, adrenal dysfunction, and rhabdomyolysis are rarely seen.

Prognosis and Treatment.

Supportive care with meticulous attention to fluid and electrolytes, control of hypertension, aggressive nutrition, and early institution of dialysis is responsible for a decrease in the mortality from this disease from 80% to less than 10% over the past 30 yr. Antibiotics should be avoided in patients with acute enteritis presumed secondary to *E. coli* 0157:H7 as they may increase the risk of developing HUS. Antithrombotic therapy has no proven therapeutic benefit in HUS. Prospective controlled studies assessing the value of plasmapheresis in HUS with a diarrheal prodrome are not available. However, plasmapheresis or administration of fresh frozen plasma may be beneficial in HUS that is not associated with a diarrheal prodrome or in children with severe central nervous system involvement. Plasmapheresis or administration of fresh frozen plasma may exacerbate HUS caused by *Streptococcus pneumoniae* and should be avoided when this infection is present. Peritoneal dialysis controls fluid and electrolyte abnormalities, maintains a normal intravascular volume, and provides the opportunity for aggressive nutritional support. Also, peritoneal dialysis may contribute to the dissolution of vascular thrombi by removing fibrinolysis inhibitors and circulating plasminogen activating inhibitor-1, thereby promoting endogenous fibrinolytic pathways. A preliminary report of a phase II clinical trial in Canada using Synsorb-PK, a silicon dioxide–derived univalent absorbent that binds Shiga toxin within the intestinal lumen, suggested a reduction in the risk of developing HUS in children when given within 3 days of the onset of a diarrheal prodrome. However, a final report of this trial has not been published. In vitro studies using more potent multivalent synthetic inhibitors of Shiga toxin or genetically engineered bacteria that neutralize large amounts of the Shiga toxin may show promise in reducing the incidence of diarrhea-associated HUS.

With aggressive management of acute renal failure, more than 90% of patients survive the acute phase of HUS with a diarrheal prodrome. End-stage renal disease occurs in approximately 9% of these patients. Patients recovering from the acute phase of HUS require long-term follow-up because complications such as hypertension, chronic renal insufficiency, and proteinuria may not be apparent for up to 20 years. Kidney transplants in patients with HUS can be successful, although disease recurrence may occur, particularly in cases without a diarrheal prodrome.

Chapter 511 - Upper Urinary Tract Causes of Hematuria

511.1 Interstitial Nephritis (see Chapter 524)

511.2 Toxic Nephropathy (see Chapter 525)

511.3 Cortical Necrosis (see Chapter 526)

511.4 Pyelonephritis (see Chapter 530)

511.5 Nephrocalcinosis (see Chapter 539)

511.6 Vascular Abnormalities

Hemangiomas, angiomyomas, and arteriovenous malformations of the kidneys and lower urinary tract are rare causes of hematuria. They usually present as gross hematuria and the passage of blood clots. Renal colic may develop if the upper tract is involved. The diagnosis is confirmed by angiography.

Unilateral bleeding of varicose veins of the left ureter, resulting from compression of the left renal vein between the aorta and superior mesenteric artery, is referred to as the *nutcracker syndrome*. Patients with this syndrome typically present with persistent microscopic hematuria that may be accompanied by proteinuria, lower abdominal pain, flank pain, or orthostatic hypotension. Diagnosis is confirmed by Doppler ultrasonography, computed tomography, or magnetic resonance angiography.

Takemura T, Iwasa H, Yamamoto S, et al: Clinical and radiological features in four adolescents with nutcracker syndrome. *Pediatr Nephrol* 2000; 14:1002–1005.

511.7 Renal Vein Thrombosis

Epidemiology.

Renal vein thrombosis (RVT) occurs in two distinct patterns. In newborns and

infants, RVT is commonly associated with asphyxia, dehydration, shock, sepsis, and infants born to mothers with diabetes mellitus. In older children, RVT is seen in patients with nephrotic syndrome, cyanotic heart disease, inherited hypercoagulable states, and following exposure to angiographic contrast agents.

Pathogenesis.

RVT begins in the intrarenal venous circulation and may spread to the main renal vein and inferior vena cava. Thrombus formation is mediated by endothelial cell injury resulting from hypoxia, endotoxin, or contrast media. Other contributing factors include (1) hypercoagulability from either nephrotic syndrome or genetic mutations such as factor V Leiden; (2) hypovolemia and diminished vascular blood flow associated with septic shock, dehydration, or nephrotic syndrome; and (3) intravascular sludging due to polycythemia.

Clinical Manifestations.

The development of RVT is usually heralded by the sudden onset of gross hematuria and unilateral or bilateral flank masses. Patients may also present with microscopic hematuria, flank pain, hypertension, or oliguria. RVT is usually unilateral. Bilateral RVT results in acute renal failure.

Diagnosis.

The diagnosis of RVT is suggested by the development of hematuria and flank masses in a patient with predisposing clinical factors. Most patients also have a microangiopathic hemolytic anemia and thrombocytopenia. Ultrasonography shows marked enlargement, whereas radionuclide studies reveal little or no renal function in the affected kidney(s). Doppler flow studies of the inferior vena cava and renal vein confirm the diagnosis. Contrast studies should be avoided to minimize the risk of further vascular damage.

Differential Diagnosis.

The differential diagnosis of RVT includes other causes of hematuria that are associated with microangiopathic hemolytic anemia or renal enlargement. These include hemolytic-uremic syndrome, hydronephrosis, polycystic kidney disease, Wilms tumor, abscess, or hematoma.

Treatment.

The primary treatment of RVT consists of supportive care including correction of fluid and electrolyte imbalance and treatment of renal insufficiency. Treatment with anticoagulation or thrombolytic agents including streptokinase, urokinase, or recombinant tissue plasminogen activator remains controversial. Patients with thrombosis of the inferior vena cava may require surgical thrombectomy. Children with severe hypertension refractory to antihypertensive medications may require nephrectomy.

Prognosis.

Perinatal mortality from RVT has decreased significantly over the past 20 yr. However, partial or complete renal atrophy is a common sequela of RVT in the neonate leading to renal insufficiency, renal tubular dysfunction, and systemic hypertension. These complications are also seen in older children, although recovery of renal function is common in children with RVT due to nephrotic syndrome or cyanotic heart disease.

511.8 Idiopathic Hypercalciuria

This entity, which may be inherited as an autosomal dominant disorder, may present as recurrent gross hematuria, persistent microscopic hematuria, dysuria, or abdominal pain in the absence of stone formation. Hypercalciuria may be caused by conditions resulting in hypercalcemia, such as hyperparathyroidism, vitamin D intoxication, immobilization, and sarcoidosis. Also, hypercalciuria may be associated with Cushing syndrome, corticosteroid therapy, tubular dysfunction secondary to Fanconi syndrome (i.e., Wilson disease, oculocerebrorenal syndrome), Williams syndrome, distal renal tubular acidosis, or Bartter syndrome. Finally, hypercalciuria may be seen in patients with Dent disease, which is an X-linked form of nephrolithiasis associated with hypophosphatemic rickets. Although microcrystal formation and irritation are believed to mediate symptoms, the precise mechanism by which the hypercalciuria causes hematuria or dysuria is unknown.

The *diagnosis* of hypercalciuria is confirmed by a 24-hour urinary calcium excretion exceeding 4?mg/kg. A screening test for hypercalciuria in patients who cannot collect a timed urine specimen may be performed on a random urine specimen by measuring the calcium and creatinine concentrations. A urine calcium to creatinine ratio (mg/mg) exceeding 0.2 suggests hypercalciuria, although normal ratios may be as high as 0.8 in infants younger than 7 mo of age.

If untreated, hypercalciuria leads to nephrolithiasis in approximately 15% of cases. Oral thiazide diuretics may normalize urinary calcium excretion by stimulating calcium reabsorption in the distal tubule. Such therapy may halt the gross hematuria or dysuria and prevent nephrolithiasis. However, the precise indications for thiazide *treatment* remain controversial. In patients with persistent gross hematuria or

dysuria, therapy is initiated with hydrochlorothiazide at a dosage of 1–2?mg/kg/24?hr as a single morning dose. The dosage is titrated upward until the 24-hour urinary calcium excretion is less than 4?mg/kg and the clinical manifestations resolve. After 1 yr of treatment, hydrochlorothiazide is usually discontinued but may be resumed if gross hematuria, nephrolithiasis, or dysuria recurs. During hydrochlorothiazide therapy, the serum potassium level should be monitored periodically to avoid hypokalemia. Potassium citrate at a dose of 1?mEq/kg/24?hr may also be beneficial, particularly in patients with low urinary citrate excretion and symptomatic dysuria. Sodium restriction is important because calcium excretion parallels that of sodium excretion. Importantly, dietary calcium restriction is not recommended because of the obligate requirement for growth and lack of evidence demonstrating a reduction in urinary calcium levels.

Chapter 512 - Hematologic Diseases Causing Hematuria

512.1 Sickle Cell Nephropathy

Gross or microscopic hematuria may be seen in children with sickle cell disease or sickle trait. Signs and symptoms resolve spontaneously in the majority of patients (see Chapter 454.1). The hematuria presumably results from microthrombosis secondary to sickling in the relatively hypoxic, acidic, hypertonic renal medulla where vascular stasis is present. Ischemia, papillary necrosis, and interstitial fibrosis may also be present in these patients. Additional clinical manifestations of sickle cell nephropathy include polyuria caused by a urinary concentrating defect, renal tubular acidosis, and proteinuria associated

---

with a glomerular lesion resembling focal segmental glomerulosclerosis or membranoproliferative glomerulonephritis. Sickle cell nephropathy may eventually lead to hypertension and renal insufficiency that may progress to end-stage renal disease. **REFERENCES**

Saborio P, Scheinman JI: Sickle cell nephropathy. *J Am Soc Nephrol* 1999; 10:187.

512.2 Coagulopathies and Thrombocytopenia

Gross or microscopic hematuria may be associated with inherited or acquired disorders of coagulation (hemophilia, disseminated intravascular coagulation, thrombocytopenia). In these cases, however, hematuria is not usually the presenting complaint but develops after other manifestations (see Part XX , Section 7).

Chapter 513 - Anatomic Abnormalities Associated with Hematuria

513.1 Congenital Anomalies

Gross or microscopic hematuria may be associated with many types of different malformations of the urinary tract. The sudden onset of gross hematuria after minor trauma to the flank is frequently associated with ureteropelvic junction obstruction or cystic kidneys.

513.2 Autosomal Recessive Polycystic Kidney Disease

Also known as *infantile polycystic disease*, autosomal recessive polycystic kidney disease (ARPKD) is an autosomal recessive disorder occurring with an incidence of 1:10,000 to 1:40,000. Although the gene for ARPKD has not been identified, genetic linkage studies have mapped a candidate locus for this disease to the short arm of chromosome 6.

Pathology.

Both kidneys are markedly enlarged and grossly show innumerable cysts throughout the cortex and medulla. Microscopic studies demonstrate microcysts radiating from the medulla to the cortex located primarily within the collecting tubules and ducts, although transient proximal tubule cysts have been reported in the fetus. Development of progressive interstitial fibrosis and tubular atrophy during advanced stages of disease eventually leads to renal failure. Liver involvement is characterized by bile duct proliferation and ectasia as well as by hepatic fibrosis that is indistinguishable from congenital hepatic fibrosis or Caroli disease.

Clinical Manifestations.

The typical child presents with bilateral flank masses during the neonatal period or early infancy. ARPKD may be associated with oligohydramnios, pulmonary hypoplasia, respiratory distress, and spontaneous pneumothorax in the neonatal period. Potter facies and other components of the oligohydramnios sequence including low-set ears, micrognathia, flattened nose, limb positioning defects, and growth deficiency may be present. Hypertension is usually noted within the first few weeks of life and is often severe. Urine output is usually not diminished, although oliguria and acute renal failure may be seen. Transient hyponatremia, often in the presence of acute renal failure, is common in the neonatal period and frequently

responds to diuresis. Renal function is usually impaired but may be normal in 20–30% of patients. Infrequently, ARPKD presents beyond infancy with renal insufficiency, hypertension, or hepatosplenomegaly related to hepatic fibrosis.

In the newborn, clinical evidence of liver disease by radiologic or laboratory assessment is present in about 45% of children. However, patients with ARPKD are at risk for developing (1) ascending cholangitis, varices, and hypersplenism related to portal hypertension and (2) progressive liver dysfunction, which rarely leads to overt liver failure and cirrhosis. A subset of older children with ARPKD may present with hepatosplenomegaly and display mild renal disease that is discovered incidentally during imaging studies of the abdomen.

Diagnosis.

The diagnosis of ARPKD is strongly suggested by bilateral palpable flank masses in an infant with pulmonary hypoplasia, oligohydramnios, and hypertension and the absence of renal cysts in the parents. Markedly enlarged and uniformly hyperechogenic kidneys with poor corticomedullary distinction are commonly seen on ultrasonography (Fig. 513–1). Also, the diagnosis is supported by clinical/laboratory signs of hepatic fibrosis, pathologic findings of ductal plate abnormalities seen on liver biopsy, anatomic and pathologic proof of ARPKD in a sibling, or parental consanguinity. The differential diagnosis includes other causes of bilateral renal enlargement, such as multicystic dysplasia, hydronephrosis, Wilms tumor, and bilateral renal vein thrombosis. Prenatal diagnostic testing using genetic linkage analysis is available in families with at least one affected child and identified informative markers.

Treatment.

The treatment of ARPKD is supportive. Aggressive ventilatory support is often necessary in the neonatal period owing to pulmonary hypoplasia and hypoventilation. Careful management of hypertension, fluid and electrolyte abnormalities, and clinical manifestations of renal insufficiency is essential. Children with severe respiratory failure or feeding intolerance from enlarged kidneys may require unilateral or bilateral nephrectomies, prompting the need for renal replacement therapy.

Figure 513.2-1 Ultrasound examination of a neonate with autosomal recessive polycystic kidney disease demonstrating renal enlargement (9?cm) and increased diffuse echogenicity with complete loss of corticomedullary differentiation resulting from multiple small cystic interfaces.

Prognosis.

Although approximately 30% of patients die in the neonatal period of complications from pulmonary hypoplasia, modern neonatal respiratory techniques and renal replacement therapies have increased the 10-year survival of children surviving beyond the 1st year of life to over 80%. Fifteen-year survival is estimated at 70–80%. End-stage renal disease is seen in over 50% of children and usually occurs during the 1st decade of life. As a result, dialysis and renal transplantation have become standard therapies for these children. Morbidity and mortality in the older child is related to complications from chronic renal failure and liver disease.

513.3 Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary human kidney disease. The autosomal dominant pattern of inheritance occurs with an incidence of 1 in 500 to 1 in 1000. Approximately 85% of patients with ADPKD map to the *PKD1* gene on the short arm of chromosome 16, which encodes polycystin, a transmembrane glycoprotein. Another 10–15% of ADPKD map to the *PKD2* gene on the long arm of chromosome 4, which encodes polycystin 2, a proposed nonselective cation channel. Remaining patients may map to other loci yet to be determined.

Pathology.

Both kidneys are enlarged and show cortical and medullary cysts originating from all regions of the nephron.

Clinical Presentation.

Although symptomatic ADPKD commonly presents in the 4th or 5th decade of life, symptoms, including gross or microscopic hematuria, bilateral flank pain, abdominal masses, hypertension, and urinary tract infection, may be seen in children and neonates. Renal ultrasonography usually demonstrates multiple bilateral macrocysts (Fig. 513–2), although unilateral disease may be seen in the early phase of the disease.

Figure 513.3-2 Ultrasound examination of an 18-mo-old boy with autosomal dominant polycystic kidney disease demonstrating renal enlargement (10?cm) and two large cysts.

ADPKD is a systemic disorder affecting many organ systems. For example, cysts may be present within the liver, pancreas, spleen, and ovaries. Intracranial aneurysms, which appear to cluster within certain families, are an important cause of mortality in adults but are rarely reported in children. Mitral valve prolapse is seen in approximately 12% of children. Hernias and intestinal diverticula may also be seen in

these children.

Diagnosis.

ADPKD is confirmed by the presence of enlarged kidneys with bilateral macrocysts in a patient with an affected first-degree relative. Absence of a family history of ADPKD does not preclude this diagnosis because affected family members may have silent disease or the affected child may have a new mutation that occurs in 5–10% of cases. Among patients with genetically defined ADPKD, screening renal ultrasonography results may be normal in up to 20% by 20 yr of age and less than 5% by 30 yr of age.

Prenatal diagnosis is suggested from the presence of enlarged kidneys with or without cysts on ultrasonography in families with known ADPKD. Prenatal DNA testing is available in families with affected members whose disease is linked to the *PKD1* or *PKD2* genes.

The differential diagnosis includes renal cysts associated with glomerulocystic kidney disease, tuberous sclerosis, and von Hippel-Lindau disease, which may be inherited in an autosomal dominant pattern. The neonatal manifestations of ADPKD and ARPKD may be indistinguishable.

Treatment and Prognosis.

Treatment of ADPKD is primarily supportive. Control of blood pressure is critical because the rate of disease progression in ADPKD correlates with the presence of hypertension.

Although neonatal ADPKD may be lethal, long-term patient and renal survival is possible for children surviving the neonatal period. Presentation of ADPKD in older children has a favorable prognosis, with normal renal function during childhood seen in over 80% of children.

513.4 Trauma

Blunt or penetrating injury to the abdomen may injure a kidney. Gross or microscopic hematuria, flank pain, and abdominal rigidity may occur; associated injuries may be present. Urethral trauma may result from crushing-type injury, frequently associated with a fractured pelvis, or from direct injury. The injury is suspected when gross blood appears at the external meatus.

513.5 Renal Tumors (see Chapter 491)

Chapter 514 - Lower Urinary Tract Causes of Hematuria

514.1 Infectious Causes of Cystitis and Urethritis

Gross or microscopic hematuria may be associated with bacterial, mycobacterial, or viral infections of the bladder (see Chapter 530). The occurrence of hematuria may be related to the depth and severity of the inflammatory reaction within the bladder wall.

Urethritis may present as gross or microscopic hematuria, usually in conjunction with urgency and pyuria. Urine cultures occasionally reveal bacteria, *Ureaplasma,* or *Chlamydia* but are usually negative. A history of trauma should be sought. The disorder frequently resolves spontaneously. In children older than 8 yr of age, a 10-day course of doxycycline is the treatment of choice in conjunction with a urinary analgesic such as phenazopyridine for relief of pain. If conservative management fails, cystoscopy may be required to determine the nature of any underlying abnormality such as ulceration or inflammation.

514.2 Hemorrhagic Cystitis

Hemorrhagic cystitis (see also Chapter 240) is defined as acute or chronic bleeding of the bladder. Patients with hemorrhagic cystitis often present with gross hematuria and dysuria. In severe forms, bleeding may lead to a decrease in blood hemoglobin levels. Hemorrhagic cystitis may occur in response to chemical toxins (cyclophosphamide, penicillins, busulfan, thiotepa, dyes, insecticides), viruses (adenovirus types 11 and 21, polyoma BK virus, influenza A), radiation, and amyloidosis. Hydration and the use of MESNA disulfide, which inactivates cyclophosphamide metabolites, helps to protect the bladder from the chemical irritation related to the use of intravenous cyclophosphamide. Administration of oral cyclophosphamide in the morning followed by aggressive oral hydration throughout the remainder of the day is very effective in minimizing the risk of hemorrhagic cystitis. Bladder irrigation with saline, alum, silver nitrate, or aminocaproic acid may be necessary in more severe forms of this disorder. Gross hematuria associated with viral hemorrhagic cystitis usually resolves within 1 wk.

DeVries CR, Freiha FS: Hemorrhagic cystitis: A review. *J Urol* 1990; 143:1–9.

514.3 Heavy Exercise

Gross or microscopic hematuria may follow vigorous exercise. Exercise hematuria is rare in females and can be associated with dysuria. The color of the urine may vary from red to black. Blood clots may be present in the urine. Findings on urine culture, intravenous pyelography, voiding cystourethrography, and cystoscopy are normal in most patients. This seems to be a benign condition, and the hematuria generally resolves within 48?hr after cessation of exercise. The absence of red blood cell casts or evidence of renal disease and the presence of dysuria and blood clots in some patients suggest that the source of bleeding lies in the lower urinary tract. Rhabdomyolysis with myoglobinuria or hemoglobinuria must be considered in the differential diagnosis when associated with exercise.

Section 3 - *Conditions Particularly Associated with Proteinuria*

Beth A. Vogt
Ellis D. Avner

Chapter 515 - Introduction to the Child with Proteinuria

In a general pediatric practice the demonstration of proteinuria on a routine screening urinalysis is a common occurrence. As many as 10% of children aged 8–15 yr will test positive for proteinuria by urinary dipstick at some time. The challenge is to differentiate the child with proteinuria related to renal disease from the otherwise healthy child with transient or other benign forms of proteinuria.

Proteinuria is commonly detected by the urine dipstick test, which offers a qualitative assessment of urinary protein excretion. Dipsticks detect primarily albuminuria and are less sensitive for other forms of proteinuria (e.g., low molecular weight proteins, Bence Jones protein, gamma globulins). The depth of color of the dipstick reaction increases in a semi-quantitative manner with increasing urinary protein concentration. The dipstick is reported as negative, trace (10–20?mg/dL), 1+ (30?mg/dL), 2+ (100?mg/dL), 3+ (300?mg/dL), and 4+ (1000–2000?mg/dL).

False-negative test results may occur in patients with dilute urine (specific gravity < 1.005) or in disease states in which the predominant urinary protein is not albumin. False-positive test results may be seen in patients with gross hematuria, contamination with antiseptic agents (chlorhexidine and benzalkonium chloride), urinary pH greater than 7.0, or phenazopyridine therapy. Most importantly, the dipstick may be falsely positive in patients with highly concentrated urine. A dipstick should be considered positive for protein only if it registers greater than or equal to 1+ (30?mg/dL) in a urine sample in which the specific gravity is less than or equal to 1.015. If the specific gravity is greater than 1.015, the dipstick must read greater than or equal to 2+ to be considered clinically significant.

Because the dipstick reaction offers only a qualitative measurement of urinary protein excretion, persistent proteinuria should be quantitated using a more precise method. A timed (12–24?hr) urine collection remains the traditional method of quantitation of urinary protein excretion.

A reasonable upper limit of normal protein excretion in healthy children is 150?mg/24?hr (0.15?g/24?hr). More specifically, normal protein excretion in children is defined as less than or equal to 4?mg/m^2 /hr, abnormal is defined as 4–40?mg/m^2 /hr, and nephrotic range is defined as more than 40?mg/m^2 /hr.

Determination of the protein/creatinine (Upr/UCr) ratio on a random urine specimen is another alternative to quantitating proteinuria and is useful when a timed urine collection is not practical. This ratio is calculated by measuring the urinary protein (mg/dL) and creatinine (mg/dL) concentrations in a random urine specimen. Ratios less than 0.5 in children younger than 2 yr of age and less than 0.2 in children 2 yr of age or older suggest normal protein excretion. A ratio greater than 3 suggests nephrotic-range proteinuria. Upr/Ucr ratios have been shown to have a high correlation with protein excretion determinations by timed urine collection.

Chapter 516 - Transient Proteinuria

The majority of children found to have a positive urinary dipstick for protein will subsequently have normal dipstick values. Of the 10% of children found to have proteinuria by a single dipstick measurement, only 1% had persistent proteinuria when measured on four separate occasions. This phenomenon, called transient proteinuria, may be caused by a temperature greater than 38.3°C (101°F) (see Chapter 161), exercise (see Chapter 675), dehydration, cold exposure, congestive heart failure, seizure, or stress. The proteinuria usually does not exceed 2+ on the dipstick. The mechanism of transient proteinuria is unknown. No evaluation is needed for children with transient proteinuria.

Chapter 517 - Orthostatic (Postural) Proteinuria

Orthostatic proteinuria is the most common cause of persistent proteinuria in school-aged children and adolescents, occurring in up to 60% of children with persistent proteinuria. Children with this condition are usually asymptomatic, and the condition is discovered on routine urinalysis. Individuals with orthostatic proteinuria excrete normal or slightly increased amounts of protein in the supine position. However, in the upright position, urinary protein excretion is increased up to 10-fold, up to 1,000?mg/24?hr (1?g/24?hr). Hematuria, hypertension, and renal dysfunction are absent.

In a child with persistent asymptomatic proteinuria, orthostatic proteinuria should be ruled out before any other evaluation is undertaken. One alternative is to obtain resting (supine) and active (upright) urine samples and perform a dipstick test for protein or evaluate the protein/creatinine ratio.

The absence of proteinuria in the resting (supine) sample and the presence of proteinuria in the active (upright) sample confirms the diagnosis of orthostatic proteinuria. A less convenient, but more exact method of comparing resting and active urinary protein excretion is a split 24-hour urine collection. A finding of essentially normal protein excretion in the supine collection and increased protein excretion in the upright collection establishes the proteinuria as orthostatic.

The cause of orthostatic proteinuria is unknown, although altered renal hemodynamics, partial renal vein obstruction, and circulating immune complexes are possible causes. Long-term follow-up studies in adults suggest that orthostatic proteinuria is a benign process, but similar data are not available for children. Therefore, long-term follow-up of children is prudent to monitor patients for evidence of renal disease, including hematuria, hypertension, diminished renal function, or proteinuria exceeding 1,000?mg/24?hr.

Chapter 518 - Fixed Proteinuria

Individuals found to have persistent significant proteinuria in both the resting (supine) and active (upright) positions are classified as having fixed proteinuria. Such proteinuria may be caused by either glomerular or tubular disorders.

518.1 Glomerular Proteinuria

Proteinuria may be seen in a variety of glomerular disorders as a result of increased permeability of the glomerular capillary wall (Box 518–1). Glomerular proteinuria may range from less than 1?g to more than 30?g/24?hr. Glomerular proteinuria may be termed *selective* (loss of plasma proteins of molecular weight up to and including albumin) or *nonselective* (loss of albumin and of larger molecular weight proteins such as IgG). The determination of urinary protein selectivity, however, is generally of little clinical value, because of the considerable overlap among various forms of renal disease.

Glomerular proteinuria should be suspected in any patient with protein excretion of more than 1?g/24?hr or accompanying hypertension, hematuria, or renal dysfunction. Causes include postinfectious glomerulonephritis, focal segmental glomerulosclerosis, mesangial proliferative glomerulonephritis, membranous nephropathy, membranoproliferative glomerulonephritis,

lupus nephritis, IgA nephropathy, Henoch-Schönlein purpura nephritis, amyloidosis, diabetic nephropathy, sickle cell nephropathy, and Alport's syndrome.

Initial evaluation of a child having persistent fixed proteinuria should include measurement of serum creatinine, 24-hr urinary protein excretion, serum albumin level, and C3 level. In asymptomatic patients with low-grade proteinuria (150–1,000?mg/24?hr) in whom all other findings are normal, renal biopsy may not be indicated because the underlying process is transient/resolving (i.e., acute postinfectious glomerulonephritis) or because specific pathologic features of a chronic renal disease may not yet be apparent. Such patients should have periodic re-evaluation consisting of a physical examination and blood pressure determination, urinalysis, and measurement of serum creatinine and 24-hr urinary protein excretion. Indications for renal biopsy include increasing proteinuria in excess of 1,000?mg/24 and/or the development of hematuria, hypertension, or diminished renal function.

Yoshikawa N, Kitagawa K, Ohta K, et al: Asymptomatic constant isolated proteinuria in children. *J Pediatr* 1991; 119:375.

518.2 Tubular Proteinuria

Fixed low-grade proteinuria (usually < 1?g/24?hr) may be a sign of a variety of renal disorders that involve the tubulointerstitial compartment of the kidney. In the healthy state, large amounts of proteins of lower molecular weight than albumin are filtered by the glomerulus and reabsorbed in the proximal tubule. Injury to the proximal tubules may result in diminished reabsorptive capacity and the loss of these low molecular weight proteins in the urine.

Tubular proteinuria (see Box 518–1) may be seen in acquired and inherited disorders and may be associated with other defects of proximal tubular function, such as glycosuria, phosphaturia, bicarbonate wasting, and aminoaciduria. Tubular proteinuria rarely presents a diagnostic dilemma because the underlying disease is usually detected before the proteinuria.

Asymptomatic patients having persistent proteinuria generally have glomerular rather than tubular proteinuria. In occult cases, glomerular and tubular proteinuria can be distinguished by electrophoresis of the urine. In tubular proteinuria, little or no albumin is detected, whereas in glomerular proteinuria the major protein is albumin.

Chapter 519 - Nephrotic Syndrome

Nephrotic syndrome is primarily a pediatric disorder and is 15 times more common in children than adults. The incidence is 2–3/100,000 children per year, and the vast majority of affected children will have steroid-sensitive minimal change disease. The characteristic features of nephrotic syndrome are heavy proteinuria (>3.5?g/24?hr in adults or 40?mg/m^2 /hr in children), hypoalbuminemia (<2.5?g/dL), edema, and hyperlipidemia.

Etiology.

Most children (90%) with nephrotic syndrome have a form of the idiopathic nephrotic syndrome. Causes of idiopathic nephrotic syndrome include minimal change disease (85%), mesangial proliferation (5%), and focal segmental glomerulosclerosis (10%). The remaining 10% of children with nephrotic syndrome have secondary nephrotic syndrome related to glomerular diseases such as membranous nephropathy or membranoproliferative glomerulonephritis (Table 519–1).

Pathophysiology.

The underlying abnormality in nephrotic syndrome is an increase in permeability of the glomerular capillary wall, which leads to massive proteinuria and hypoalbuminemia. The cause of the increased permeability is not well understood. In minimal change disease, it is possible that T-cell dysfunction leads to alteration of cytokines, which causes a loss of negatively charged glycoproteins within the glomerular capillary wall.

In focal segmental glomerulosclerosis, a plasma factor, perhaps produced by lymphocytes, may be responsible for the increase in capillary wall permeability.

Although the mechanism of edema formation in nephrotic syndrome is incompletely understood, it seems likely that, in most instances, urinary protein loss leads to hypoalbuminemia, which causes a decrease in the plasma oncotic pressure and transudation of fluid from the intravascular compartment to the interstitial space. The reduction in intravascular volume decreases renal perfusion pressure, activating the renin-angiotensin-aldosterone system, which stimulates tubular reabsorption of sodium. The reduced intravascular volume also stimulates the release of antidiuretic hormone, which enhances the reabsorption of water in the collecting duct. Because of the decreased plasma oncotic pressure, fluid shifts into the interstitial space, exacerbating the edema.

This theory does not apply to all patients with nephrotic syndrome, however, because some patients actually have increased intravascular volume with diminished plasma levels of renin and aldosterone. Therefore, other factors, including a primary renal avidity for sodium and water, may be involved in

TABLE 519-1 -- Summary of Primary Renal Diseases That Present As Idiopathic Nephroti Syndrome

**Approximate frequency as a cause of idiopathic nephrotic syndrome. About 10% of adult nephrotic syndrome is due to various diseases that usually present as acute glomerulonephritis.*
† Relative risk.

the formation of edema in some patients with nephrotic syndrome.

In the nephrotic state, serum lipid levels (cholesterol, triglycerides) are elevated for two reasons. Hypoalbuminemia stimulates generalized hepatic protein synthesis, including synthesis of lipoproteins. In addition, lipid catabolism is diminished, as a result of reduced plasma levels of lipoprotein lipase, related to increased urinary losses of this enzyme.

519.1 Idiopathic Nephrotic Syndrome

Approximately 90% of children with nephrotic syndrome have idiopathic nephrotic

syndrome. Idiopathic nephrotic syndrome includes three histologic types: minimal change disease, mesangial proliferation, and focal segmental glomerulosclerosis. Some experts believe that these three disorders represent three separate diseases with a similar clinical presentation, whereas others believe that these disorders represent a spectrum of a single disease.

Pathology.

In *minimal change disease* (85% of total cases), the glomeruli appear normal or show a minimal increase in mesangial cells and matrix. Findings on immunofluorescence microscopy are typically negative, and electron microscopy simply reveals effacement of the epithelial cell foot processes. More than 95% of children with minimal change disease respond to corticosteroid therapy.

Mesangial proliferation (5% of total cases) is characterized by a diffuse increase in mesangial cells and matrix on light microscopy. Immunofluorescence microscopy may reveal trace to 1+ mesangial IgM and/or IgA staining. Electron microscopy reveals increased numbers of mesangial cells and matrix as well as effacement of the epithelial cell foot processes. Approximately 50% of patients with this histologic lesion respond to corticosteroid therapy.

In *focal segmental glomerulosclerosis* (10% of total cases), glomeruli show mesangial proliferation and segmental scarring on light microscopy (Fig. 519–1). Immunofluorescence microscopy shows IgM and C3 staining in the areas of segmental sclerosis. Electron microscopy shows segmental scarring of the glomerular tuft with obliteration of the glomerular capillary lumen. A similar lesion may be seen with HIV infection, vesicoureteral reflux, and intravenous heroin abuse. Approximately 20% of patients with focal segmental glomerulosclerosis respond

Figure 519.1-1 Glomerulus from a patient with steroid-resistant nephrotic syndrome, showing mesangial hypercellularity and an area of sclerosis in the lower portion. (×250.)

to prednisone. The disease is frequently progressive, ultimately involving all glomeruli, and leads to end-stage renal failure in most patients.

Clinical Manifestations.

The idiopathic nephrotic syndrome is more common in males than in females (2:1) and most commonly appears between the ages of 2 and 6 yr. It has been reported as early as 6 mo of age and throughout adulthood. The initial episode and subsequent relapses may follow minor infections and, occasionally, reactions to insect bites, bee stings, or poison ivy. Children usually present with mild edema, which is initially noted around the eyes and in the lower extremities. Nephrotic syndrome may initially be misdiagnosed as an allergic disorder because of the periorbital swelling that decreases throughout the day. With time, the edema becomes generalized, with the development of ascites, pleural effusions, and genital edema. Anorexia, irritability, abdominal pain, and diarrhea are common; hypertension and gross hematuria are uncommon. The differential diagnosis of the child with marked edema includes protein-losing enteropathy, hepatic failure, congestive heart failure, acute or chronic glomerulonephritis, and protein malnutrition.

Diagnosis.

The urinalysis reveals 3+ or 4+ proteinuria; microscopic hematuria may be present in 20% of children. Urinary protein excretion exceeds 3.5?g/24?hr in adults and 40?mg/m^2 /hr in children. Spot urine protein to creatinine ratio exceeds 2.0. The serum creatinine value is usually normal, but it may be increased because of diminished renal perfusion resulting from contraction of the intravascular volume. The serum albumin level is generally less than 2.5?g/dL, and the serum cholesterol and triglyceride levels are elevated. C3 and C4 levels are normal. Renal biopsy is not required for diagnosis in most children (see Treatment).

Treatment.

Children with the first episode of nephrotic syndrome and mild to moderate edema may be managed as outpatients. Affected children may attend school and participate in physical activities as tolerated. The pathophysiology and treatment of nephrotic syndrome should be carefully reviewed with the family to enhance their understanding of their child's disease. Sodium intake should be reduced by the initiation of a low sodium diet and may be normalized when the child enters remission. Although there are no data to support their safety or efficacy, oral diuretics are used by many clinicians for children with nephrotic syndrome. Because of the possibility of increasing the risk of thromboembolic complications, diuretic use should be judicious and should be carefully supervised by a pediatric nephrologist.

Children with severe symptomatic edema, including large pleural effusions, ascites, or severe genital edema, should be hospitalized. In addition to sodium restriction, fluid restriction may be necessary if the child is hyponatremic. A swollen scrotum may be elevated with pillows to enhance the removal of fluid by gravity. Diuresis may be augmented by intravenous administration of chlorothiazide (10?mg/kg/dose every 12?hr) or metolazone (0.1?mg/kg/dose bid) followed by furosemide 30?min later (1–2?mg/kg/dose q 12?hr).

Intravenous administration of 25% human albumin (0.5?g/ kg/12?hr) is often necessary when this potent combination is used. Such therapy mandates close monitoring of volume status, serum electrolyte balance, and renal function. Symptomatic volume overload, with hypertension and heart failure, is a potential complication of parenteral albumin therapy.

Children with onset of nephrotic syndrome between 1 and 8 yr of age are likely to have steroid-responsive minimal change disease; therefore, steroid therapy may be initiated without renal biopsy. Children with features that make minimal change disease less likely (hematuria, hypertension, renal insufficiency, hypocomplementemia, age < 1 yr or > 8 yr) should be considered for renal biopsy before treatment.

In children with presumed minimal change disease, prednisone should be administered (after confirming a negative PPD test) at a dose of 60?mg/m^2 /day (maximum daily dose, 80?mg), divided into two to three doses for at least 4 consecutive weeks. There is some evidence that an initial 6 wk course of daily steroid treatment may lead to a lower relapse rate, although the frequency of steroid-induced side effects is significantly higher. Eighty to 90% of children will respond to steroid therapy (urine trace or negative for protein for 3 consecutive days), with the median time to remission of 10 days. The vast majority of children who will respond to prednisone therapy will do so within the first 4 wk of treatment.

After the initial 4–6 wk course, the prednisone dose should be tapered to 40?mg/m^2 /day given every other day as a single morning dose. The alternate-day dose is then slowly tapered and discontinued over the next 2–3 mo. Children who continue to have proteinuria (2+ or greater) after 8 wk of steroid therapy are considered steroid resistant, and a diagnostic renal biopsy should be performed.

Many children with nephrotic syndrome will experience at least one relapse (3–4+ proteinuria plus edema). Although relapse rates of 60–80% have been noted in the past, the relapse rate in children treated with longer initial steroid courses may be as low as 30–40%.

Relapses should be treated with daily divided-dose prednisone at the doses noted earlier until the child enters remission (urine trace or negative for protein for 3 consecutive days). The prednisone dose is then changed to alternate-day dosing and tapered over 1–2 mo.

A subset of patients will relapse while on alternate-day steroid therapy or within 28 days of stopping prednisone therapy. Such patients are termed *steroid dependent.* Patients who respond well to prednisone therapy but relapse four or more times in a 12-mo period are termed *frequent relapsers.* Children who fail to respond to prednisone therapy within 8 wk are termed *steroid resistant.*

Steroid-dependent patients, frequent relapsers, and steroid- resistant patients may be candidates for alternative agents, particularly if the child suffers severe corticosteroid toxicity (cushingoid appearance, hypertension, cataracts, and/or growth failure). Cyclophosphamide has been shown to prolong the duration of remission and to reduce the number relapses in children with frequently relapsing and steroid-dependent nephrotic syndrome. The potential side effects of the drug (neutropenia, disseminated varicella, hemorrhagic cystitis, alopecia, sterility, and increased risk of future malignancy) should be carefully reviewed with the family before initiating treatment. The dose of cyclophosphamide is 2–3?mg/kg/24?hr given as a single dose, for a total duration of 8–12 wk. Alternate-day prednisone therapy is often continued during the course of cyclophosphamide administration. During cyclophosphamide therapy, the white blood cell count must be monitored weekly and the drug withheld if the count falls below 5,000/mm^3 .

An additional option for the child with complicated nephrotic syndrome is high-dose pulse methylprednisolone. Methylprednisolone is usually given as a 30-mg/kg bolus (maximum 1,000?mg), with the first 6 doses given every other day, followed by a tapering regimen for periods up to 18 mo. Cyclophosphamide may be added to this regimen in selected patients.

Prolonged administration of cyclosporine (3–6?mg/kg/24?hr) has also been effective in maintaining a prolonged remission in children with nephrotic syndrome and is useful as a steroid- sparing agent. Children must be monitored for side effects, including hypertension, nephrotoxicity, hirsutism, and gingival hyperplasia. Unfortunately, most children who respond to cyclosporine therapy tend to relapse when the medication is discontinued.

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II blockers may be helpful as an adjunct therapy to reduce proteinuria in steroid-resistant patients.

Complications.

Infection is the major complication of nephrotic syndrome. Children in relapse have increased susceptibility to bacterial infections owing to urinary losses of immunoglobulins and properdin factor B, defective cell-mediated immunity, immunosuppressive therapy, malnutrition, and edema/ascites acting as a potential "culture medium." Spontaneous bacterial peritonitis is the most frequent type of infection, although sepsis, pneumonia, cellulitis, and urinary tract infections may also be seen. Although *Streptococcus pneumoniae* is the most common organism causing peritonitis, gram-negative bacteria such as *Escherichia coli* may also be encountered. Because fever and physical findings may be minimal in the presence of corticosteroid therapy, a high index of suspicion, prompt evaluation (including cultures of blood and peritoneal fluid), and early initiation of antibiotic therapy are critical. The role of prophylactic antibiotic therapy during relapse remains controversial.

All children with nephrotic syndrome should receive polyvalent pneumococcal vaccine (if not previously immunized), ideally administered when the child is in remission and off of daily prednisone therapy. Children with a negative varicella titer should be given varicella vaccine when in remission or on a low dose of alternate-day steroids. Nonimmune nephrotic children in relapse exposed to varicella should receive varicella zoster immune globulin (VZIG) within 72?hr of exposure. Influenza vaccine should be given on a yearly basis.

Children with nephrotic syndrome are also at increased risk for thromboembolic events. The incidence of this complication in children is 2–5%, which represents a much lower risk than that of adults with nephrotic syndrome. Both arterial and venous thromboses may be seen, including renal vein thrombosis, pulmonary embolus, sagittal sinus thrombosis, and thrombosis of indwelling arterial and venous catheters. The risk of thrombosis is related to increased prothrombotic factors (fibrinogen, thrombocytosis, hemoconcentration, relative immobilization) and decreased fibrinolytic factors (urinary losses of antithrombin ill, proteins C and S). Prophylactic anticoagulation is not recommended in children unless they have had a previous thromboembolic event. Overaggressive diuresis should be avoided and use of indwelling catheters limited because these factors may increase the likelihood of clotting complications.

Prognosis.

The majority of children with steroid-responsive nephrotic syndrome have repeated relapses, which generally decrease in frequency as the child grows older.

Although there is no proven way to predict an individual child's course, those children who respond to steroids rapidly and those who have no relapses during the first 6 mo after diagnosis tend to follow an infrequently relapsing course. It is important to indicate to the family that the child with steroid-responsive nephrotic syndrome will not develop chronic renal failure, that the disease is generally not hereditary, and that the child (in the absence of prolonged cyclophosphamide therapy) will remain fertile. To minimize the psychological effects of the condition, the physician should emphasize that the child should be considered normal when in remission and may have unrestricted diet and activity, without the need for urine testing for protein.

Children with steroid-resistant nephrotic syndrome, most often caused by focal segmental glomerulosclerosis, generally have a much poorer prognosis (see Chapter 528). These children develop progressive renal insufficiency, ultimately leading to end-stage renal failure requiring dialysis or renal transplantation. Recurrent nephrotic syndrome develops in 30–50% of transplant recipients with focal segmental glomerulosclerosis. Plasmapheresis, plasma protein absorption onto protein A–based columns, high-dose cyclosporine or tacrolimus, and

angiotensin-converting enzyme (ACE) inhibitors may reduce proteinuria in these patients. **REFERENCES**

519.2 Secondary Nephrotic Syndrome

Nephrotic syndrome also occurs as a secondary feature of many forms of glomerular disease. Membranous nephropathy, membranoproliferative glomerulonephritis, postinfectious glomerulonephritis, lupus nephritis, and Henoch-Schönlein purpura nephritis may all have a nephrotic component. In general, secondary nephrotic syndrome should be suspected in patients with age > 8 yr, hypertension, hematuria, renal dysfunction, extrarenal symptomatology (rash, arthralgias, etc.), or depressed serum complement levels.

In certain areas of the world, malaria and schistosomiasis are the leading causes of nephrotic syndrome. Other infectious agents associated with nephrotic syndrome include hepatitis B virus, hepatitis C virus, filaria, leprosy, and HIV.

Nephrotic syndrome has been associated with malignancy, particularly in the adult population. In patients with solid tumors, such as carcinomas of the lung and gastrointestinal tract, the renal pathology often resembles membranous glomerulopathy. Immune complexes composed of tumor antigens and tumor-specific antibodies presumably mediate the renal involvement. In patients with lymphomas, particularly Hodgkin lymphoma, the renal pathology most often resembles minimal change disease. The proposed mechanism of the nephrotic syndrome is that the lymphoma produces a lymphokine that increases glomerular capillary wall permeability. Nephrotic syndrome may develop before or after the malignancy is detected, may resolve as the tumor regresses, and may return if the tumor recurs.

Nephrotic syndrome has also developed during therapy with numerous drugs and chemicals. The histologic picture may resemble membranous glomerulopathy (penicillamine, captopril, gold, nonsteroidal anti-inflammatory drugs, mercury compounds), minimal change disease (probenecid, ethosuximide, methimazole, lithium), or proliferative glomerulonephritis (procainamide, chlorpropamide, phenytoin, trimethadione, paramethadione).

519.3 Congenital Nephrotic Syndrome

Infants who develop nephrotic syndrome within the first 3 mo of life are considered to have congenital nephrotic syndrome. The most common cause of this syndrome is Finnish type congenital nephrotic syndrome, an autosomal recessive disorder that is most common in populations of Scandinavian descent (1:8,000 incidence). This type of congenital nephrotic syndrome is caused by a mutation in the *NPHS1* gene located on chromosome 19, which encodes a protein, nephrin. Nephrin is a key component of the slit diaphragm of the glomerular epithelial cell and is thought to play an essential role in the normal function of the glomerular filtration barrier. The major pathologic features of the Finnish type of this syndrome are dilatation of the proximal tubules, mesangial hypercellularity, and glomerular sclerosis.

Infants with the Finnish type of congenital nephrotic syndrome present with massive proteinuria (detectable in utero by increased a-fetoprotein), a large placenta, and marked edema. Additional clinical features include prematurity, respiratory distress, and separation of the cranial sutures. The natural history of the disease is one of persistent edema, recurrent infections, and progressive renal failure with death by the age of 5 yr. Corticosteroids and immunosuppressive agents are of no value.

ACE inhibitors, indomethacin, and unilateral nephrectomy may diminish proteinuria and ameliorate the nephrotic state. However, the preferred treatment includes bilateral nephrectomy, chronic dialysis, aggressive nutritional support, and eventual kidney transplantation. In families at risk for the Finnish type of congenital nephrotic syndrome, antenatal diagnosis is suggested by an elevated amniotic fluid a-fetoprotein level and the diagnosis may be confirmed by DNA analysis.

Other causes of congenital nephrotic syndrome include congenital infections such as syphilis, toxoplasmosis, rubella, and cytomegalovirus. HIV and hepatitis B have also been reported to cause nephrotic syndrome in the neonatal period. The nephrotic state, which is generally less severe than the Finnish type of congenital nephrotic syndrome, may improve or resolve with treatment of the underlying infection.

Diffuse mesangial sclerosis is a rare glomerular disease seen in a minority of children with congenital nephrotic syndrome. The characteristic pathologic finding is progressive sclerosis of the glomerular mesangium, and the clinical picture is one of rapid loss of renal function, with end-stage renal disease developing within months to years. Diffuse mesangial sclerosis may occur as an isolated disease or as part of *Denys-Drash syndrome,* a condition also characterized by Wilms tumor and male pseudohermaphroditism, caused by a mutation in the Wilms tumor gene *(WT1)* on chromosome 11.

Section 4 - *Tubular Disorders*

Chapter 520 - Tubular Function

Katherine MacRae Dell
Ellis D. Avner

Water and electrolytes are freely filtered at the level of the glomerulus. Thus, the electrolyte content of “ultrafiltrate” at the beginning of the proximal tubule is similar to that of plasma. Carefully regulated processes of tubular reabsorption and/or tubular secretion determine final water content and electrolyte composition of urine. As a general principle, “bulk” movement of solute tends to occur in the proximal portions of the nephron, whereas fine adjustments tend to occur distally. Modern advances in molecular biology have helped to delineate the role of specific nephron segments in regulating ion and water transport and the diseases that occur as a result of abnormalities in these processes. This chapter provides an overview of normal tubular function and tubular disorders. (See also Chapter 45 .)

Sodium.

Sodium is essential in maintaining extracellular fluid balance and, thus, volume status. The kidney is capable of effecting large changes in sodium excretion in a variety of normal and pathologic states. There are four main sites of sodium transport. Approximately 60% of sodium is absorbed in the proximal tubule by coupled transport with glucose or amino acids, 25% in the ascending loop of Henle (bumetanide-sensitive sodium-potassium 2 chloride transporter, NKCC2), and 15% in the distal tubule (thiazide-sensitive sodium chloride cotransporter, NCCT) and collecting tubule (epithelial sodium channel, ENaC). Under normal circumstances, the urinary excretion of sodium approximates the sodium intake (80–250?mEq/24?hr for an adult who consumes a typical American diet) minus 1–2?mEq/kg/24?hr required for normal metabolic processes. However, in states of volume depletion (e.g., dehydration, blood loss) or decreased effective circulating blood volume (e.g., septic shock, hypoalbuminemic states, or congestive heart failure), there may be a dramatic decrease in urinary sodium excretion to as low as 1?mEq/L. Changes in volume status are detected by baroreceptors in the atria, afferent arteriole, and the carotid sinus and by the macula densa, which detects changes in chloride delivery. The major hormonal mechanisms mediating sodium balance include the renin-angiotensin-aldosterone (RAA) axis, atrial natriuretic factor (ANF), and norepinephrine. Angiotensin II and aldosterone increase sodium reabsorption in the proximal tubule and distal tubules, respectively. Norepinephrine, released in response to volume depletion, does not directly act on tubular transport mechanisms but impacts on sodium balance by decreasing renal blood flow and thus decreasing the filtered load of sodium, as well as stimulating renin release. With more severe volume depletion antidiuretic hormone (ADH) is also released (see Chapter 522). Sodium excretion is promoted by atrial natriuretic factor (ANF) and suppression of renin.

Potassium.

Extracellular potassium homeostasis is very tightly regulated, because small changes in plasma potassium concentrations have dramatic effects on cardiac, neural, and neuromuscular function. Essentially all filtered potassium is fully reabsorbed in the proximal tubule. Therefore, urinary excretion of potassium is completely dependent on tubular secretion by potassium channels present in the principal cells of the collecting tubule. Factors that promote potassium secretion include aldosterone, increased sodium delivery to the distal nephron, and increased urine flow rate.

Calcium.

A significant portion of filtered calcium (65%) is reabsorbed in the proximal tubule. Additional calcium is reabsorbed in the ascending loop of Henle by passive movement between cells (paracellular absorption) in a process driven by sodium chloride reabsorption and potassium recycling into the lumen. Calcium uptake in this nephron segment is regulated by an extracellular calcium receptor (CaR). Factors that promote calcium reabsorption include parathyroid hormone (PTH, released in response to hypocalcemia), thiazide diuretics, and volume depletion. Factors that promote calcium excretion include sodium intake (either orally or by infusion of sodium-containing intravenous fluids) and loop diuretics such as furosemide.

Phosphate.

The majority of filtered phosphate is reabsorbed in the proximal tubule. Reabsorption is increased by endogenous or exogenous calcitriol (1,25-dihydroxyvitamin D) and inhibited by PTH.

Magnesium.

About 25% of filtered magnesium is reabsorbed in the proximal tubule. Modulation of renal magnesium excretion occurs primarily in the ascending loop of Henle, with some contribution of the distal convoluted tubule. Although specific magnesium

transporters have been identified, the precise mechanisms by which they are regulated remain unclear.

Acidification and Concentrating Mechanisms.

These are addressed in the sections on renal tubular acidosis and nephrogenic diabetes insipidus (see Chapters 521 and 522).

Developmental Considerations.

Tubular transport capabilities of neonates (especially premature infants) and young infants are generally less than that of adults. Although nephrogenesis (the formation of new glomerular/tubular units) is complete by about 36 wk gestation, significant tubular maturation occurs during infancy. Renal tubular immaturity, reduced glomerular filtration rate, decreased concentrating gradient, and diminished responsiveness to antidiuretic hormone are characteristic of young infants. These factors can contribute to impaired electrolyte and water regulation and acid-base homeostasis, particularly during times of acute illness.

Chapter 521 - Renal Tubular Acidosis

Renal tubular acidosis (RTA) is a disease state characterized by a normal anion gap metabolic acidosis resulting from either

impaired bicarbonate reabsorption or impaired urinary acid (hydrogen ion) excretion. Both inherited and acquired primary and secondary forms exist. There are three main forms of RTA: proximal (type II) RTA, distal (type I) RTA, and hyperkalemic (type IV) RTA. Mixed lesions (e.g., those with elements of types I and II RTA), which occur primarily in patients with inherited carbonic anhydrase deficiency, have been designated as type III RTA by some authors.

Normal Urinary Acidification.

Urinary acidification involves two processes: bicarbonate reabsorption and hydrogen ion excretion. Bicarbonate reabsorption results in reclamation of the filtered bicarbonate but does not result in net acid secretion. Approximately 85% of the filtered bicarbonate is reabsorbed in the proximal tubule. In infants, bicarbonate reabsorption is less efficient, and renal bicarbonate excretion may occur at serum concentrations less than 22?mmol/L. Bicarbonate itself is not directly absorbed through a specific transporter but instead is absorbed by an indirect process. Proximal tubule reabsorption of bicarbonate begins with secretion of a hydrogen ion in exchange for a sodium ion. The hydrogen ion in the tubular lumen binds with bicarbonate and, under the influence of carbonic anhydrase, is converted to carbon dioxide and water. Carbon dioxide then diffuses into the proximal tubular cell, where a series of chemical reactions result in the creation of a bicarbonate molecule (which enters the peritubular capillary) and a hydrogen ion, which can participate in further buffering of bicarbonate in the tubular lumen. The remaining 15% of bicarbonate is reabsorbed distally. Secretion of the daily acid load (approximately 1?mEq/kg/24?hr produced during normal cellular processes) is accomplished by hydrogen ion secretion (mediated by a H^+ ATPase present in the intercalated cells of the collecting tubule), ammoniagenesis, and formation of titratable acids (formed when H^+ ions are buffered by organic acids such as phosphate).

521.1 Proximal (Type II) Renal Tubular Acidosis

Katherine MacRae Dell
Ellis D. Avner

Pathogenesis.

Proximal RTA results from impaired proximal tubule bicarbonate reabsorption. Isolated forms of inherited or acquired proximal RTA occur, although they are generally rare. Isolated autosomal dominant forms, as well as an autosomal recessive form associated with ocular abnormalities, have been reported. More typically, proximal RTA occurs as a component of global proximal tubule dysfunction or Fanconi syndrome. The latter condition is characterized by low molecular weight proteinuria, glycosuria, phosphaturia, aminoaciduria, and proximal RTA. Both autosomal dominant and autosomal recessive forms of primary Fanconi syndrome occur. In addition, secondary Fanconi syndrome may occur as a component of one of several inherited renal tubular disorders or in acquired disease states. The causes of proximal RTA and Fanconi syndrome are outlined in Box 521–1 . Many of these causes are inherited disorders. Two diseases, *cystinosis* and *Lowe syndrome,* are addressed in detail later. Other inherited forms of Fanconi syndrome, discussed elsewhere in the text, include *galactosemia* (see Chapter 76.2), *hereditary fructose intolerance* (see Chapter 76.3), *tyrosinemia* (see Chapter 74.2), and *Wilson disease* (see Chapters 338.2 and 590.3). *Dent disease*, or X-linked nephrolithiasis, is discussed in Chapter 523.3 . In children, an important form of secondary Fanconi syndrome is exposure to ifosfamide, a component of many treatment regimens for Wilms tumor and other solid tumors.

Cystinosis is a systemic disease caused by a defect in the metabolism of cystine, which results in accumulation of cystine crystals in most of the major organs of the body, notably kidney, liver, eye, and brain. It occurs at an incidence of 1:100,000–1:200,000. In

Box 521.1-1. Classification of Renal Tubular Acidosis

certain populations, such as French Canadians, the incidence is much higher. At least three clinical patterns have been described. Young children with the most severe form of the disease (*infantile* or *nephropathic cystinosis*) present in the first 2 yr of life with severe tubular dysfunction and growth failure. If the disease is not treated, the children develop end-stage renal disease by the end of their first decade. A milder form of the disease presents in adolescents and is characterized by less severe tubular abnormalities and a slower progression to renal failure. A benign adult form with no renal involvement also exists. Cystinosis is caused by mutations in the *CTNS* gene, which encodes a novel protein, cystinosin. Although the precise function of cystinosin has not been fully

delineated, it is thought to be an H^+ -driven lysosomal cystine transporter. Genotype-phenotype studies in patients with severe nephropathic cystinosis demonstrate complete loss of cystinosin function, whereas patients with milder clinical disease still express partially functional protein.

Patients with nephropathic cystinosis present with *clinical manifestations* reflecting their pronounced tubular dysfunction and Fanconi syndrome, including polyuria and polydipsia, growth failure, and rickets. Fever, caused by dehydration or diminished

sweat production, is common. Patients are typically fair skinned and blond, owing to diminished pigmentation. Photophobia occurs. With progressive tubulointerstitial fibrosis, renal insufficiency is invariant. Retinopathy and impaired visual acuity occur, as well as hypothyroidism, hepatosplenomegaly, and delayed sexual maturation.

The *diagnosis* of cystinosis is suggested by the detection of cystine crystals in the cornea. Confirmation is made by measurement of leukocyte cystine content. Prenatal testing is available for at-risk families.

Treatment is directed at correcting the metabolic abnormalities associated with Fanconi syndrome or chronic renal failure. In addition, specific therapy is available with cysteamine, which binds to cystine, converts it to cysteine, and facilitates transport out of the lysosome, thereby depleting cystine from tissues. Oral cysteamine does not achieve adequate levels in ocular tissues, so additional therapy with cysteamine eye drops is required. Early initiation of the drug may prevent or delay deterioration of renal function. Patients with growth failure that does not improve with cysteamine may benefit from treatment with growth hormone. Renal transplantation is a viable option in patients with renal failure; but with prolonged survival, additional complications may become evident, including central nervous system abnormalities, muscle weakness, swallowing dysfunction, and pancreatic insufficiency.

Lowe syndrome (also called *oculocerebrorenal syndrome of Lowe*) is a rare X-linked disorder characterized by congenital cataracts, mental retardation, and Fanconi syndrome. The disease is caused by mutations in the *OCRL1* gene, which encodes the phosphatidylinositol polyphosphate 5-phosphatase protein. The abnormalities seen in Lowe syndrome are thought to be due to abnormal transport of vesicles within the Golgi apparatus. Histologically, kidneys show nonspecific tubulointerstitial changes. Thickening of glomerular basement membrane and changes in the proximal tubule mitochondria are also seen.

Patients with Lowe syndrome typically present in infancy with cataracts, progressive growth failure, hypotonia, and Fanconi syndrome. Blindness and renal insufficiency often develop. Characteristic behavioral abnormalities are also seen, including tantrums, stubbornness, stereotypy (repetitive behaviors), and obsessions. There is no specific therapy for the renal disease or neurologic deficits. Cataract removal is generally required.

Clinical Manifestations of Proximal RTA and Fanconi Syndrome.

Patients with isolated, sporadic, or inherited proximal RTA commonly present with growth failure in the first year of life. Additional symptoms may include polyuria, dehydration (due to sodium losses), anorexia, vomiting, constipation, and hypotonia. Patients with primary Fanconi syndrome will have additional symptoms secondary to phosphate wasting such as rickets. Those with systemic diseases will present with additional signs and symptoms specific to their underlying disease. A non–anion gap metabolic acidosis will be present. Urinalysis in patients with isolated proximal RTA is generally unremarkable. The urine pH is acidic (<5.5), because distal acidification mechanisms are intact in these patients. In contrast, urinary indices in patients with Fanconi syndrome demonstrate varying degrees of phosphaturia, aminoaciduria, glycosuria, uricosuria, and elevated urinary sodium or potassium. Depending on the nature of the underlying disorder, laboratory evidence of chronic renal insufficiency, including elevated serum creatinine, may be present.

521.1 Distal (Type I) Renal Tubular Acidosis

Katherine MacRae Dell
Ellis D. Avner

Pathogenesis.

Distal RTA occurs as the result of impaired distal urinary acidification (hydrogen ion secretion). Primary or secondary causes can result in damaged or impaired functioning of one or more transporters or proteins involved in the acidification process, including the H^+/ATPase, the HCO_3^-/Cl^- anion exchangers or the components of the aldosterone pathway. Because of impaired hydrogen ion excretion, urine pH cannot be reduced below 5.5, despite the presence of severe metabolic acidosis. Loss of sodium bicarbonate results in hyperchloremia and hypokalemia. Hypercalciuria is usually present and may lead to nephrocalcinosis or nephrolithiasis. Chronic metabolic acidosis also impairs urinary citrate excretion. Hypocitraturia further increases the risk of calcium deposition in the tubules. Bone disease is common, resulting from mobilization of organic components from bone to serve as buffers to chronic acidosis. Both primary sporadic or inherited forms occur. As with proximal RTA, distal RTA can also occur as a complication of either inherited or acquired diseases of the distal tubules.

Clinical Manifestations.

Patients with distal RTA share common features with those of proximal RTA, including non–anion gap metabolic acidosis and growth failure. However, distinguishing features of distal RTA include nephrocalcinosis and hypercalciuria. The phosphate and massive bicarbonate wasting characteristic of proximal RTA is generally absent.

Causes of primary and secondary distal RTA are listed in Box 521–1 . Although rare, three specific inherited forms of distal RTA have been identified, including an autosomal recessive form associated with sensorineural deafness.

Medullary sponge kidney is a relatively rare sporadic disorder in children, although not uncommon in adults. It is characterized by cystic dilatation of the terminal portions of the collecting ducts as they enter the renal pyramids. Ultrasonographically, patients often have medullary nephrocalcinosis (Fig. 521–1).

Figure 521.1-1 Ultrasound examination of a child with distal renal tubular acidosis demonstrating medullary nephrocalcinosis

---

Although patients with this condition typically maintain normal renal function through adulthood, complications include nephrolithiasis, pyelonephritis, hyposthenuria

(inability to concentrate urine), and distal RTA. Associations of medullary sponge kidney with Beckwith-Wiedemann syndrome or hemihypertrophy have been reported.

521.2 Hyperkalemic (Type IV) Renal Tubular Necrosis

Katherine MacRae Dell
Ellis D. Avner

Pathogenesis.

Type IV RTA occurs as the result of impaired aldosterone production (hypoaldosteronism) or impaired renal responsiveness to aldosterone ("pseudo" hypoaldosteronism). Because aldosterone has a direct effect on the H^+ ATPase responsible for hydrogen secretion, acidosis results. In addition, aldosterone is a potent stimulant for potassium secretion in the collecting tubule. Loss of aldosterone effect results in hyperkalemia. This further affects acid-base status by inhibiting ammoniagenesis and, thus, hydrogen ion excretion. Aldosterone deficiency typically occurs as a result of adrenal gland disorders such as Addison disease or congenital adrenal hyperplasia (CAH). In children, aldosterone unresponsiveness is a more common cause of type IV RTA. This may occur transiently, during an episode of acute pyelonephritis or acute urinary obstruction, or chronically, particularly in infants and children with a history of obstructive uropathy. The latter patients may have significant hyperkalemia, even in instances when renal function is normal or only mildly impaired. Rare examples of inherited forms of type IV RTA have been identified.

Clinical Manifestations.

Patients with type IV RTA, like those with types I and II RTA, may present with growth failure in the first few years of life. Polyuria and dehydration (from salt wasting) are common. Rarely, patients (especially those with pseudohypoaldosteronism type 1) will present with life-threatening hyperkalemia. Patients with obstructive uropathies may present acutely with signs and symptoms of pyelonephritis, such as fever, vomiting, and foul-smelling urine. Laboratory tests reveal a hyperkalemic non–anion gap metabolic acidosis. Urine may be alkaline or acidic. Elevated urine sodium levels with inappropriately low urine potassium levels reflect the absence of aldosterone effect.

Diagnosis.

The first step in the evaluation of a patient with suspected RTA is to confirm the presence of and nature of the metabolic acidosis, identify electrolyte abnormalities, assess renal function, and rule out other causes of metabolic acidosis, such as diarrhea. Metabolic acidosis associated with diarrheal dehydration is extremely common, and acidosis will generally improve with correction of volume depletion. However, patients with protracted diarrhea may deplete their total-body bicarbonate stores and may have persistent acidosis despite apparent restoration of volume status. In those instances in which a patient has a recent history of severe diarrhea, full evaluation for RTA should be delayed for several days to permit adequate time for reconstitution of total-body bicarbonate stores. If acidosis persists beyond a few days in this setting, additional studies are indicated.

Serum electrolytes, blood urea nitrogen, calcium, phosphorus, and creatinine and pH should be obtained by venous puncture. Traumatic blood draws (such as heel stick specimens) or prolonged specimen transport time can lead to falsely low bicarbonate levels, often in association with an elevated serum potassium value. True hyperkalemic acidosis is consistent with type IV RTA, whereas the finding of normal or low potassium suggests type I or II. The anion gap should be calculated using the formula $[Na^+] - [Cl^- + HCO_3^-]$. Values of less than 12 demonstrate the absence of an anion gap. Values more than 20 are highly suggestive of the presence of an anion gap. If such an anion gap is found, then other diagnoses (e.g., lactic acidosis, inborn errors of metabolism, or ingestions) should be investigated. If tachypnea is noted, an arterial blood gas analysis may be obtained to rule out the possibility of a primary respiratory alkalosis driving a compensatory metabolic acidosis. The finding of an acidic pH is consistent with a primary metabolic acidosis. A detailed history, with particular attention to growth and development, recent or recurrent diarrheal illnesses, and family history of mental retardation, failure to thrive, end-stage renal disease, or infant deaths or miscarriages is essential. Physical examination should determine growth parameters and volume status as well as the presence of dysmorphic features suggesting an underlying syndrome. Once the presence of a non–anion gap metabolic acidosis is confirmed, urine pH may help distinguish distal from proximal causes. A urine pH of less than 5.5 in the presence of acidosis suggests proximal RTA, whereas patients with distal RTA typically have a urine pH of more than 6.0. The urine anion gap ($[\text{Urine } Na^+ + \text{Urine } K^+] - \text{Urine } Cl^-$) is sometimes calculated to confirm the diagnosis of distal RTA. A positive gap suggests a deficiency of ammoniagenesis and, thus, the possibility of a distal RTA. A negative gap is consistent with proximal tubule bicarbonate wasting (or gastrointestinal bicarbonate wasting). A urinalysis should also be obtained to determine the presence of glycosuria, proteinuria, or hematuria suggesting the possibility of more global tubular damage or dysfunction. Random or 24-hr urine calcium and creatinine measurements will identify hypercalciuria. A renal ultrasound should be obtained to identify underlying structural abnormalities such as obstructive uropathies as well as to determine the presence of nephrocalcinosis.

Treatment and Prognosis.

The mainstay of therapy in all forms of RTA is bicarbonate replacement. Patients with proximal RTA often require large quantities of bicarbonate, up to 20?mEq/kg/24?hr in the form of sodium bicarbonate or sodium citrate solution (Bicitra or Stohl's solution). The base requirement for distal RTAs is generally in the range of 2–4?mEq/kg/24?hr, although patient requirements may vary. Patients with Fanconi syndrome generally require phosphate supplementation. Patients with distal RTA should be monitored for the development of hypercalciuria. Those with symptomatic hypercalciuria (e.g., recurrent episodes of gross hematuria), nephrocalcinosis, or nephrolithiasis may require thiazide diuretics to decrease urine calcium excretion. Patients with type IV RTA may require chronic treatment for hyperkalemia with sodium-potassium exchange resin (Kayexalate®).

Prognosis is dependent to a large part on the nature of any underlying disease, if present. Patients with treated isolated proximal or distal RTA will generally demonstrate improvement in growth, provided serum bicarbonate levels can be maintained in the normal range. Patients with systemic illness and Fanconi

syndrome may have ongoing difficulties with growth failure, rickets, and signs and symptoms related to their underlying disease.

521.3 Rickets Associated with Renal Tubular Acidosis

Russell W. Chesney

Rickets may be present in primary renal tubular acidosis (RTA), particularly in type II or proximal RTA. See Chapters 44.10 and 697 . Hypophosphatemia and phosphaturia are common in these syndromes, which are characterized by hyperchloremic metabolic acidosis, various degrees of bicarbonaturia, and, frequently, hypercalciuria and hyperkaluria. Bone demineralization without overt rickets usually is detected in type I and distal RTA. The metabolic bone disease may be characterized by bone pain, growth retardation, osteopenia, and, occasionally, pathologic fractures. Although acute metabolic acidosis in vitamin D–deficient animals may impair the conversion of 25(OH)D to 1,25$(OH)_2$ D, resulting in reduced levels of this active metabolite, the circulating levels of 1,25$(OH)_2$ D in patients with either type of RTA are normal. If patients with RTA have azotemia and loss of renal mass, serum 1,25$(OH)_2$ D levels are often reduced.

Bone demineralization in distal RTA probably relates to dissolution of bone, because the calcium carbonate in bone may serve as a buffer against the metabolic acidosis that is due to the hydrogen ions retained by patients with RTA.

Administration of sufficient bicarbonate to reverse acidosis stops bone dissolution and the hypercalciuria that is common in distal RTA. Proximal RTA is treated with both bicarbonate and oral phosphate supplements to heal bone disease. Doses of phosphate similar to those used in familial hypophosphatemia or Fanconi syndrome should be used (see Chapter 696). Vitamin D is needed to offset the secondary hyperparathyroidism that complicates oral phosphate therapy.

Chapter 522 - Nephrogenic Diabetes Insipidus

Katherine MacRae Dell
Ellis D. Avner

Congenital nephrogenic diabetes insipidus (NDI) is a rare disorder of water metabolism characterized by an inability to concentrate urine, even in the presence of antidiuretic hormone (ADH). The most common pattern of inheritance is as an X-linked recessive disorder. Rarely, affected females are seen, presumably owing to unfavorable X chromosome inactivation. Rare autosomal recessive forms have also been described, with males and females affected equally. The clinical phenotype of autosomal recessive forms is similar to that of the X-linked form. Secondary (acquired), either partial or complete, forms of NDI may be seen in disorders affecting renal tubular function including obstructive uropathies, acute or chronic renal failure, cystic diseases, interstitial nephritis, nephrocalcinosis, or toxic nephropathy due to hypokalemia, hypercalcemia, lithium, or amphotericin B.

Pathogenesis.

The ability to concentrate urine (and thus absorb water) requires the presence of an intact concentrating gradient in the renal medulla and the ability to modulate water permeability in the collecting tubule. The latter is mediated by ADH (also called arginine vasopressin [AVP]), which is synthesized in the hypothalamus and stored in the posterior pituitary. Under basal situations, the collecting tubule is impermeable to water. However, in response to increased serum osmolarity (as detected by osmoreceptors in the hypothalamus) and/or severe volume depletion, ADH is released into the systemic circulation. It then binds to its receptor, vasopressin V2 (AVPR2), on the basolateral membrane of the collecting tubule cell. Binding of the hormone to its receptor activates a cyclic adenosine monophosphate (AMP)-dependent cascade that results in movement of preformed water channels (aquaporin 2 [AQP2]) to the luminal membrane of the collecting duct, rendering it permeable to water. Defects in the *AVPR2* gene cause the more common X-linked form of NDI. Mutations in the *AQP2* gene have been identified in patients with the rarer autosomal recessive form. Prenatal testing is available for families at risk for X-linked NDI. Patients with secondary forms of NDI may have ADH resistance owing to defective aquaporin expression (e.g., lithium intoxication). More commonly, secondary ADH resistance occurs as the result of loss of the hypertonic medullary gradient due to solute diuresis or tubular damage, resulting in the inability to absorb sodium or urea.

Clinical Manifestations.

Patients with congenital NDI typically present in the newborn period with massive polyuria, volume depletion, hypernatremia, and hyperthermia. Irritability and crying are common features. Constipation and poor weight gain are also seen. After multiple episodes of hypernatremic dehydration, patients may have developmental delay and mental retardation. Enuresis, caused by large urine volumes, is common. Because of the need to consume large volumes of water during the day, patients often have diminished appetite and poor food intake. However, even with adequate caloric supplementation, patients still exhibit growth abnormalities. Patients with congenital NDI also exhibit behavioral problems, including hyperactivity and short-term memory problems. Patients with the secondary form generally present later in life, primarily with hypernatremia and polyuria. Associated symptoms such as developmental delay and behavioral abnormalities are less common in this latter group.

Diagnosis.

The diagnosis is suggested in a male infant with polyuria, hypernatremia, and dilute urine. Simultaneous serum and urine osmolality measurements should be obtained. If the serum osmolality value is 290?mOsm/kg or higher with a urine osmolality value of less than 290?mOsm/kg, a formal water deprivation test is not necessary. Because the differential diagnosis includes causes of central diabetes insipidus, the inability to respond to ADH (and thus the presence of NDI) should then be confirmed by the administration of vasopressin (10–20?µg intranasally or 0.1–0.2?U/kg IM) followed by serial urine and serum osmolality measurements hourly for 4 hours. In patients with possible “partial” or secondary diabetes insipidus, in whom the initial serum osmolality value may be above 290?mOsm/kg, a water deprivation test should be considered. Fluids should be withheld and urine and serum osmolalities measured periodically until the serum osmolality value is above 290?mOsm/kg; vasopressin is then given as before. Criteria for premature termination of a water deprivation test include a decrease in body weight of more than 3%. If NDI is confirmed or suspected, additional evaluation should include a detailed history to assess for toxic exposures, determination of renal function by serum creatinine and blood urea nitrogen levels, and a renal ultrasound to evaluate for obstructive uropathies or cystic disease. Because of massive urine output, patients with congenital NDI may have nonobstructive hydronephrosis of varying severity.

Treatment and Prognosis.

Treatment of NDI includes (1) maintenance of adequate fluid intake and access to free water; (2) minimizing urine output by limiting solute load with a low-osmolar, low-sodium diet; and (3) administering medications directed at decreasing urine output. Human milk or a low solute formula, such as Similac PM 60/40, is preferred. Most infants with congenital NDI require gastrostomy or nasogastric feedings to ensure consistent fluid administration throughout the day and

night. Sodium intake in older patients should be less than 0.7?mEq/kg/24?hr. Thiazide diuretics (2–3?mEq/kg/24?hr of hydrochlorothiazide) effectively induce sodium loss and stimulate proximal tubule reabsorption of water. Potassium-sparing diuretics, in particular, amiloride (20?mg/1.73?m^2 /24?hr), are often indicated. Patients who have an inadequate response to diuretics alone may benefit from the addition of indomethacin (2?mg/kg/24?hr), which has an additive effect in reducing water excretion in some patients. Renal function must be monitored closely in such patients, because indomethacin may cause deterioration in renal function over time. Patients with secondary NDI may not require medications but should have access to free water. Such patients should have serum electrolytes and volume status monitored closely, particularly during times of superimposed acute illnesses.

Prevention of recurrent dehydration and hypernatremia in patients with congenital NDI has significantly improved the neurodevelopmental outcome of these patients. However, behavioral issues remain a significant problem. In addition, chronic use of nonsteroidal anti-inflammatory drugs may predispose patients to renal insufficiency. Prognosis of patients with secondary NDI generally depends on the nature of the underlying disease.

Chapter 523 - Bartter/Gitelman Syndromes and Other Inherited Tubular Transport Abnormalities

Katherine MacRae Dell
Ellis D. Avner

Inherited tubular transport abnormalities comprise a spectrum of rare diseases, each involving distinct nephron segments. Advances in genetics and molecular biology have delineated the pathogenesis of many of these disorders and furthered the understanding of normal mechanisms of renal water and electrolyte homeostasis.

523.1 Bartter Syndrome

Bartter syndrome is a rare form of hypokalemic metabolic alkalosis with hypercalciuria, with an autosomal recessive pattern of inheritance. Two distinct clinical subtypes of Bartter syndrome are seen. Antenatal Bartter syndrome (also called hyperprostaglandin E syndrome) typically presents in infancy and has a more severe phenotype than “classic” Bartter syndrome, including polyhydramnios, salt wasting, and severe dehydration. The milder phenotype, “classic” Bartter syndrome, presents in childhood with failure to thrive and a history of recurrent episodes of dehydration. A phenotypically related disease, Gitelman syndrome, has a distinct genetic defect and is discussed in Chapter 523.2 . A genetically distinct variant of antenatal Bartter syndrome associated with sensorineural deafness and chronic renal insufficiency has also been reported.

Pathogenesis.

The biochemical features of Bartter syndrome, including hypokalemic metabolic alkalosis with hypercalciuria, resemble those seen with loop diuretic use and reflect a defect in sodium, chloride, and potassium transport in the ascending loop of Henle. The loss of sodium and chloride, with resultant volume contraction, stimulates the renin/angiotensin II/aldosterone (RAA) axis. Aldosterone promotes sodium uptake and potassium secretion, exacerbating the hypokalemia. It also stimulates hydrogen ion secretion distally, worsening the metabolic alkalosis. Hypokalemia stimulates prostaglandins, which further activate the RAA axis. Bartter syndrome has been associated with three distinct genetic defects in loop of Henle transporters. Each contributes, in some manner, to sodium and chloride transport. Mutations in the sodium potassium 2 chloride transporter, NKCC2 (the site of action of furosemide),

or in the luminal potassium channel, ROMK, cause neonatal Bartter syndrome. Defects in the basolateral chloride channel, ClC-Kb, cause classic Bartter syndrome.

Clinical Manifestations.

A history of polyhydramnios may be elicited. Dysmorphic features, including triangular facies, protruding ears, large eyes with strabismus, and drooping mouth may be present on physical examination. Consanguinity suggests the presence of an autosomal recessive disorder. Older children may have a history of recurrent episodes of dehydration, failure to thrive, and the biochemical abnormalities noted next. Hypokalemia and metabolic alkalosis are invariant features of Bartter syndrome. Urinary calcium level is typically elevated, as are urinary potassium and sodium levels. Serum renin, aldosterone, and prostaglandin E levels are often markedly elevated, particularly in the more severe antenatal form. Blood pressure is usually normal, although patients with the antenatal form may have severe salt wasting, resulting in dehydration and hypotension. Renal function is typically normal. Nephrocalcinosis, resulting from hypercalciuria, may be seen on ultrasound examination.

Diagnosis.

The diagnosis is usually made on the basis of the clinical presentation and laboratory findings. The diagnosis in the neonatal infant is suggested by severe hypokalemia, usually less than 2.5?mmol/L, with metabolic alkalosis. Hypercalciuria is typical; hypomagnesemia is seen in a minority of patients but is more common in the Gitelman syndrome. Because features of Bartter syndrome resemble chronic loop diuretic use, diuretic abuse should be considered in the differential diagnosis, even in young children. Chronic vomiting may also give a similar clinical picture but can be distinguished by measurement of urinary chloride, which is elevated in Bartter syndrome and low in patients with chronic vomiting. Histologically, kidneys demonstrate hyperplasia of the juxtaglomerular apparatus. However, renal biopsy samples are rarely performed to diagnose this condition.

Treatment and Prognosis.

Treatment of Bartter syndrome is directed at preventing dehydration, maintaining nutritional status, and correcting hypokalemia. Potassium supplementation, often at very high doses, is required. Even with appropriate therapy, serum potassium values may not normalize, particularly in patients with the neonatal form. Infants and young children may require sodium supplementation as well. Indomethacin, a prostaglandin inhibitor, may also be effective. With close attention to electrolyte balance, volume status, and growth, the long-term prognosis is generally good. However, in a small minority of patients, chronic hypokalemia, nephrocalcinosis, and chronic indomethacin therapy can lead to chronic interstitial nephritis and chronic renal failure.

523.2 Gitelman Syndrome

Gitelman syndrome (often called a Bartter syndrome “variant”) is also a rare autosomal recessive cause of hypokalemic metabolic alkalosis, with distinct features of hypocalciuria and hypomagnesemia. Patients with Gitelman syndrome typically present later in childhood or early adulthood.

Pathogenesis.

The biochemical features of Gitelman syndrome resemble those of chronic thiazide diuretic use. Thiazides act on the sodium chloride co-transporter, NCCT, present in the distal convoluted tubule. Through linkage analysis and mutational studies, defects in the gene encoding NCCT have been demonstrated in patients with Gitelman syndrome.

Clinical Manifestations.

Patients with Gitelman syndrome typically present at a later age than those with Bartter syndrome. Patients often have a history of recurrent muscle cramps and spasms, presumably caused by low serum magnesium levels. They typically do not have a history of recurrent episodes of dehydration. Biochemical abnormalities include hypokalemia, metabolic alkalosis, and hypomagnesemia. The urinary calcium level is usually very low (in contrast to the elevated urinary calcium level often seen in Bartter syndrome), and the urinary magnesium level is elevated. Renin and aldosterone levels are usually normal, and prostaglandin E secretion is not elevated. Growth failure is less prominent in Gitelman syndrome than in Bartter syndrome, but it may be present.

Diagnosis.

The diagnosis of Gitelman syndrome is suggested in an adolescent or adult presenting with hypokalemic metabolic alkalosis, hypomagnesemia, and hypocalciuria.

Treatment.

Treatment is directed at correcting hypokalemia and hypomagnesemia with supplemental potassium and magnesium. Sodium supplementation or treatment with prostaglandin inhibitors is generally not necessary because patients typically do not have episodes of volume depletion or elevated prostaglandin E excretion.

523.3 Other Inherited Tubular Transport Abnormalities

Inherited abnormalities in distinct transporters in each segment of the nephron have now been identified and the molecular defects characterized. Renal tubular acidosis and nephrogenic diabetes insipidus are discussed in detail in Chapters 521 and 522, respectively. *Cystinuria* is an autosomal recessive disorder seen primarily in patients of Middle Eastern descent characterized by recurrent stone formation. The

disease is caused by a defective high-affinity transporter for L-cystine and dibasic amino acids present in the proximal tubule.

X-linked nephrolithiasis (Dent disease) is a disease characterized by recurrent stone formation and progression to Fanconi syndrome. Consistent with the X-linked recessive inheritance, it is seen almost exclusively in males. Dent disease is caused by mutations in the voltage-gated chloride channel, CLN5, present throughout the nephron. In the loop of Henle, activating and inactivating mutations in the calcium receptor, which mediates PTH-induced calcium uptake, cause severe hypoparathyroidism or hyperparathyroidism, respectively.

In the collecting duct, gain of function mutations of the epithelial sodium channel cause an inherited form of hypertension, *Liddle syndrome*. Patients with this disorder have constitutive sodium uptake in the collecting duct, with hypokalemia and suppressed aldosterone. Conversely, loss of function mutations cause pseudohypoaldosteronism, characterized by severe sodium wasting and hyperkalemia. A variant of the latter disorder is associated with systemic abnormalities, including defects in sweat chloride, and may resemble cystic fibrosis.

Chapter 524 - Tubulointerstitial Nephritis

Katherine MacRae Dell
Ellis D. Avner

Tubulointerstitial nephritis (TIN, also called interstitial nephritis) is the term applied to conditions characterized by tubulointerstitial inflammation and damage with relative sparing of glomeruli and vessels. Both acute and chronic primary forms exist. In addition, interstitial nephritis can be present with primary glomerular diseases as well as systemic diseases affecting the kidney.

ACUTE TUBULOINTERSTITIAL NEPHRITIS

Pathogenesis and Pathology.

The hallmarks of acute TIN are lymphocytic infiltration of the tubulointerstitium, tubular edema, and varying degrees of tubular damage. Eosinophils may be present, especially in drug-induced TIN; occasionally, granulomas occur. The pathogenesis is not fully understood, but a _T-cell–mediated immune mechanism has been postulated. A large number of medications, especially antimicrobials, anticonvulsants, and analgesics, have been implicated as etiologic agents (Box 524–1). Other causes include infections, primary glomerular diseases, and systemic diseases such as systemic lupus erythematosus (SLE).

Clinical Manifestations.

The classic presentation of acute TIN is fever, rash, and arthralgia in the setting of a rising serum creatinine value. Although the full “triad” may be noted in drug-induced TIN, many patients with acute TIN do not have all of the typical features. The rash, if present, may vary from maculopapular to urticarial and is often transient. Patients often have nonspecific constitutional symptoms of nausea, vomiting, fatigue, and weight loss. Flank pain may be present from stretching of the renal capsule from kidney enlargement. If acute TIN is caused by a systemic disease such as SLE, patients may present with specific signs and symptoms of the underlying disease. Unlike the typical presentation of oliguric acute renal failure seen with glomerular diseases, 30–40% of patients with acute TIN are nonoliguric. Peripheral eosinophilia may occur, especially with drug-induced TIN. Some degree of microscopic hematuria is invariably present, but significant hematuria or proteinuria is typically absent. One

exception is patients with TIN caused by nonsteroidal anti-inflammatory drugs (NSAIDs), who may present with the nephrotic syndrome. White blood cells and granular or hyaline casts may be present, but red blood cell casts, characteristic of glomerular disease, are rarely seen. Urine eosinophils are neither sensitive nor specific.

Diagnosis.

The diagnosis is usually made on the basis of clinical presentation and laboratory findings. A careful history of timing of disease onset in relation to drug exposure is essential in suspected drug-induced TIN. Because of the immune-mediated nature of TIN, signs or symptoms generally appear 1–2 wk after exposure. In children, antimicrobials are a common inciting agent. Concomitant with a rise in usage, NSAIDS are being

increasingly recognized as a cause of acute TIN in children. Urinalysis and serial measurements of serum creatinine and electrolytes should be monitored. A renal ultrasound is not diagnostic, but it may demonstrate enlarged, echogenic kidneys. Removal of an offending agent followed by spontaneous improvement in renal function is highly suggestive of the diagnosis, and additional testing is generally not performed. In more severe cases, in which the cause is unclear or the patient's renal function deteriorates rapidly, a renal biopsy may be indicated.

Treatment and Prognosis.

Treatment is generally supportive and directed at addressing complications of acute renal failure such as hyperkalemia or volume overload. Although definitive data are lacking, uncontrolled studies suggest that patients with significant renal impairment may benefit from a trial of corticosteroids. In those patients who show rapid improvement in renal function without treatment, prognosis is excellent. However, in cases with prolonged renal insufficiency, the prognosis is more guarded. Severe acute TIN from any cause that does not resolve may progress to chronic TIN.

CHRONIC TUBULOINTERSTITIAL NECROSIS

In children, chronic TIN most commonly occurs as the result of an underlying congenital renal disease, such as obstructive uropathy or vesicoureteral reflux (see Box 524–1). Chronic TIN can occur as an idiopathic disease, although this is more common in adults. *Juvenile nephronophthisis (JN)/medullary cystic disease complex (JN/MCKD)* is a group of inherited cystic diseases that share a common histologic phenotype of chronic TIN. JN is inherited as an autosomal recessive trait. Although rare in the United States, JN causes 10–20% of end-stage renal disease in Europe. Patients with JN typically present with polyuria, growth failure, “unexplained” anemia, and chronic renal failure in late childhood or adolescence. Variants of JN with extrarenal involvement include *Senior-Løken syndrome* (retinitis pigmentosa), Joubert syndrome, and oculomotor apraxia type Cogan. *MCKD* is an autosomal dominant disease that typically presents only in adulthood. *Tubulointerstitial nephritis with uveitis (TINU)* is a rare autoimmune syndrome of chronic TIN with anterior uveitis and bone marrow granulomas that occurs primarily in adolescent females. Finally, chronic TIN is seen in all forms of progressive renal disease, regardless of

the underlying cause, and the severity of interstitial disease is the single most important predictor of progression to end-stage renal disease.

Pathogenesis and Pathology.

As with acute TIN, the pathophysiology of chronic TIN is undefined, but data suggest that it is immune mediated. Grossly, kidneys may appear pale and small for age. Microscopically, tubular atrophy and “dropout” with interstitial fibrosis and a patchy lymphocytic interstitial inflammation are seen. Patients with juvenile nephronophthisis often have characteristic small cysts in the corticomedullary region. In primary chronic TIN, glomeruli are relatively spared until late in the disease course. Patients with chronic TIN secondary to a primary glomerular disease will have histologic evidence of the primary disease.

Clinical Manifestations.

The clinical features of chronic TIN are often nonspecific and may reflect signs and symptoms of chronic renal insufficiency. Fatigue, growth failure, polyuria, polydipsia, and enuresis are often present. Anemia is common and is a particularly prominent feature of juvenile nephronophthisis. Because tubular damage often leads to renal salt wasting, significant hypertension is unusual.

Diagnosis.

The diagnosis is suggested by signs or symptoms of renal tubular damage such as polyuria and an elevated serum creatinine value, coupled with a history suggestive of a chronic disease, such as long-standing enuresis or the presence of anemia resistant to iron therapy. Radiographic studies, in particular ultrasonography, may give additional evidence for chronicity, such as small, echogenic kidneys, corticomedullary cysts suggestive of juvenile nephronophthisis, or findings of obstructive

uropathy. A vesicocystourethrogram (VCUG) may demonstrate the presence of vesicoureteral reflux (VUR) or bladder abnormalities. In those instances in which the cause is unclear, a renal biopsy may be performed. However, in cases of advanced disease, a renal biopsy may not be diagnostic. Many end-stage kidney diseases display a common histologic appearance of tubular fibrosis and inflammation.

Treatment and Prognosis.

Treatment is directed at maintaining fluid and electrolyte balance and avoiding further exposure to nephrotoxic agents. Patients with obstructive uropathies may require salt supplementation and treatment with potassium binding resin (Kayexalate®). Prevention of infection by antibiotic prophylaxis is also important in slowing progression of renal damage in those patients. Prognosis in patients with chronic TIN is dependent, in large part, on the nature of the underlying disease. Patients with obstructive uropathy or VUR may have a variable degree of renal damage, and thus a variable course. End-stage renal disease, if it occurs, may develop over months to years. Patients with juvenile nephronophthisis uniformly progress to end-stage renal disease by adolescence.

Beth A. Vogt
Ellis D. Avner

Medications, diagnostic agents (iodinated radiographic contrast media), and chemicals may alter the kidneys directly (through reduction of renal blood flow, acute tubular necrosis, intratubular obstruction) or indirectly (through induction of an allergic or hypersensitivity reaction in the vessels or interstitium). Common nephrotoxic agents and their clinical manifestations are listed in Box 525–1 . Nephrotoxicity is frequently reversible if the noxious agent is removed.

Useful agents should not be withheld because of potential nephrotoxicity, but the following preventive measures may reduce the risks of nephrotoxicity: (1) substitution of ultrasound, magnetic resonance imaging, or radionuclide scans for studies using contrast media in patients with pre-existing renal disease; (2) substitution of non-nephrotoxic agents for nephrotoxic agents; (3) use of the lowest effective dose of the agent in conjunction with monitoring of the blood level; (4) appropriate reduction of all drug dosing in patients with renal insufficiency, guided by well-developed nomograms; (5) avoidance of simultaneous use of several nephrotoxic agents.

Chapter 526 - Cortical Necrosis

Beth A. Vogt
Ellis D. Avner

Renal cortical (and frequently medullary) necrosis represents a final common result of several types of renal injury. It usually affects both kidneys and may be patchy or involve the entire cortex.

Etiology.

In newborns, cortical necrosis is most commonly associated with hypoxic/ischemic insults caused by perinatal asphyxia, placental abruption, and twin-twin or fetal-maternal transfusion. Other causes include renal vascular thrombosis and severe congenital heart disease. After the neonatal period, cortical necrosis is most commonly seen in children with septic shock or severe hemolytic-uremic syndrome as well as in adolescents with pregnancy-related acute renal failure. Less common causes of cortical necrosis include snakebites, infectious endocarditis, cefuroxime, and therapy with antifibrinolytic drugs (tranexamic acid).

Pathology.

Involved portions of the cortex show infarction, with congestion of the glomeruli, thrombosis of the arterioles, and necrosis of the tubules.

Pathogenesis.

Cortical necrosis develops when endothelial cell injury occurs in conjunction with diminished renal cortical blood flow. Toxins or other mediators that presumably develop during shock, hemolytic-uremic syndrome, or sepsis may injure the endothelial cells and initiate intrarenal coagulation, leading to thrombosis and cortical necrosis.

Clinical Manifestations.

Cortical necrosis presents as acute renal failure developing in individuals having the previously mentioned predisposing causes. Urine output is diminished and gross and/or microscopic hematuria may be present. Hypertension is common, and thrombocytopenia may be present, as a result of renal microvascular injury.

Diagnosis.

Early in the course, the diagnosis is supported by ultrasonographic detection of normal-sized or enlarged, nonobstructed kidneys. Subsequent ultrasound evaluations show a significant decrease in renal size, suggestive of renal atrophy. Radionuclide renal scans show decreased or absent renal perfusion with delayed or absent function. The differential diagnosis includes other causes of renal failure (see Box 527–1).

Treatment and Prognosis.

Therapy is supportive and involves volume repletion, correction of asphyxia, and treatment of sepsis. Medical management of the complications of acute renal failure and supportive dialysis may be necessary. Children with cortical necrosis may have partial or no renal recovery, and the prognosis depends on the amount of surviving renal cortex. Those children with partial recovery are at increased risk for the subsequent development of chronic renal failure.

Chapter 527 - Renal Failure

Beth A. Vogt
Ellis D. Avner

527.1 Acute Renal Failure

Acute renal failure (ARF) is a clinical syndrome in which a sudden deterioration in renal function results in the inability of the kidneys to maintain fluid and electrolyte homeostasis. ARF occurs in 2–3% of children admitted to pediatric tertiary care centers and in as many as 8% of infants in the neonatal intensive care unit.

Pathogenesis.

ARF has been conventionally classified into three categories: prerenal, intrinsic renal, and postrenal (Box 527–1).

Prerenal ARF, also called prerenal azotemia, is characterized by diminished effective circulating arterial volume, which leads to inadequate renal perfusion and a decreased glomerular filtration rate (GFR). Evidence of kidney damage is absent. Common causes of prerenal ARF include dehydration, sepsis, hemorrhage, severe hypoalbuminemia, and cardiac failure. If the underlying cause of the renal hypoperfusion is reversed promptly, renal function returns to normal. If hypoperfusion is sustained, intrinsic renal parenchymal damage may develop.

Intrinsic renal ARF includes a variety of disorders characterized by renal parenchymal damage, including sustained hypoperfusion/ischemia. Many forms of glomerulonephritis, including postinfectious glomerulonephritis, lupus nephritis, Henoch-Schönlein purpura nephritis, membranoproliferative glomerulonephritis, and anti–glomerular basement membrane nephritis, may cause ARF.

Hemolytic-uremic syndrome (HUS) has been described as the most common cause of intrinsic ARF in North America (see Chapter 510). The cardinal features of HUS include ARF, microangiopathic hemolytic anemia, and thrombocytopenia. Although HUS has been linked to numerous factors, the most common predisposing factor in developed countries is hemorrhagic colitis caused by toxigenic *Escherichia coli* (OI57:H7).

Acute tubular necrosis (ATN) occurs most often in critically ill infants and children who have been exposed to nephrotoxic and/or ischemic insults. The typical pathologic process of ATN is tubular cell necrosis, although significant histologic changes are not consistently seen in patients with clinical ATN. The mechanisms of injury in ATN may include alterations in intrarenal hemodynamics, tubular obstruction, and passive backleak of the glomerular filtrate across injured tubular cells into the peritubular capillaries.

Tumor lysis syndrome is a specific form of ARF related to spontaneous or chemotherapy-induced cell lysis in patients with lymphoproliferative malignancies. This disorder is primarily

caused by obstruction of the tubules by uric acid crystals (see Chapters 487 and 491).

Acute interstitial nephritis is an increasingly common cause of ARF and is usually a result of a hypersensitivity reaction to a therapeutic agent or various infectious agents (see Chapter 524).

Postrenal ARF includes a variety of disorders characterized by obstruction of the urinary tract. In neonatal infants, congenital conditions such as posterior urethral valves and bilateral ureteropelvic junction obstruction account for the majority of cases of ARF. Other conditions such as urolithiasis, tumor (intra-abdominal or within the urinary tract), hemorrhagic cystitis, and neurogenic bladder may cause ARF in older children and adolescents. In a patient with two functioning kidneys, obstruction must be bilateral to result in ARF. In general, relief of the obstruction results in recovery of renal function except in patients with associated renal dysplasia or prolonged urinary tract obstruction.

Clinical Manifestations and Diagnosis.

A carefully taken history is critical in defining the cause of ARF. An infant with a 3-day history of vomiting and diarrhea most likely has prerenal ARF caused by volume depletion. A 6-yr-old child with a recent pharyngitis who presents with periorbital edema, hypertension, and gross hematuria most likely has intrinsic ARF related to acute postinfectious glomerulonephritis. A critically ill child with a history of protracted hypotension and exposure to nephrotoxic medications most likely has ATN. A neonate with a history of hydronephrosis on prenatal ultrasound and a palpable bladder most likely has congenital urinary tract obstruction, perhaps related to posterior urethral valves.

The physical examination must be thorough, with careful attention to volume status. Tachycardia, dry mucous membranes, and poor peripheral perfusion suggest inadequate circulating volume and the possibility of prerenal ARF. Peripheral edema, rales, and a cardiac gallop suggest volume overload and the possibility of intrinsic ARF from glomerulonephritis or ATN. The presence of a rash and arthritis may suggest systemic lupus erythematosus (SLE) or Henoch-Schönlein purpura nephritis. Palpable flank masses may suggest renal vein thrombosis, tumors, cystic disease, or urinary tract obstruction.

Laboratory Findings.

Laboratory abnormalities may include anemia (the anemia is usually dilutional or hemolytic, as in SLE, renal vein thrombosis, and HUS); leukopenia (SLE); thrombocytopenia (SLE, renal vein thrombosis, HUS); hyponatremia (dilutional); metabolic acidosis; elevated serum concentrations of blood urea nitrogen, creatinine, uric acid, potassium, and phosphate (diminished renal function); and hypocalcemia (hyperphosphatemia).

The serum C3 level may be depressed (postinfectious, SLE, or membranoproliferative glomerulonephritis), and antibodies may be detected in the serum to streptococcal (poststreptococcal glomerulonephritis), nuclear (SLE), neutrophil cytoplasmic (antineutrophil cytoplasmic antibody; Wegener granulomatosis, microscopic polyarteritis), or glomerular basement membrane (Goodpasture disease) antigens.

The presence of hematuria, proteinuria, and red blood cell or granular urine casts suggests intrinsic ARF, in particular glomerular disease. The presence of white blood cells and white blood cell casts, with low-grade hematuria and proteinuria, suggests tubulointerstitial disease. Urinary eosinophils may be present in children with drug-induced tubulointerstitial nephritis.

Urinary indices may be useful in differentiating prerenal ARF from intrinsic ARF (Table 527–1). Patients whose urine shows an elevated specific gravity (>1.020), elevated urine osmolality (Uosm > 500?mOsm/kg), low urine sodium (UNa < 20?mEq/L), and fractional excretion of sodium (FENa) less than 1% (2.5% in neonates) most likely have prerenal ARF. Those with a specific gravity less than 1.010, low urine osmolality (Uosm < 350?mOsm/kg), high urine sodium (UNa >

40?mEq/L), and FENa

TABLE 527.1-1 -- **Laboratory Indices for Prerenal vs. Intrinsic Acute**

Index	Prerenal	Intrinsic Renal
Specific gravity	>1.020	<1.010
Urine osmolality (mOsm)	>500	<350
Urine sodium (mEq/L)	<20	>40
FENa (%)	<1	>2
Blood urea nitrogen/creatinine	>20	<20

greater than 2% (> 10% in neonates) most likely have intrinsic ARF.

Chest roentgenography may reveal cardiomegaly and pulmonary congestion (fluid overload). Renal ultrasonography may reveal hydronephrosis and/or hydroureter, which are suggestive of urinary tract obstruction. Renal biopsy may ultimately be required to determine the precise cause of ARF in patients who do not have clearly defined prerenal or postrenal ARF.

Treatment

MEDICAL MANAGEMENT.

In infants and children with urinary tract obstruction, such as in a newborn with suspected posterior urethral valves, a bladder catheter should be placed immediately to ensure adequate drainage of the urinary tract. The placement of a bladder catheter may also be considered in nonambulatory older children and adolescents to accurately monitor urine output during ARF.

Determination of the volume status is of critical importance when initially evaluating a patient with ARF. If there is no evidence of volume overload or cardiac failure, intravascular volume should be expanded by intravenous administration of isotonic saline, 20?mL/kg over 30?min. In the absence of blood loss or hypoproteinemia, colloid-containing solutions are not required for volume expansion. Severe hypovolemia may require additional fluid boluses (see Chapter 57.2). Determination of the central venous pressure may be helpful if adequacy of the blood volume is in question. After volume resuscitation, hypovolemic patients generally void within 2?hr; failure to do so points toward the presence of intrinsic or postrenal ARF.

Diuretic therapy should be considered only after the adequacy of the circulating blood volume has been established. Furosemide may be administered as a single intravenous dose of 2–4?mg/kg. Bumetanide (0.1?mg/kg) may be given as an alternative to furosemide. If urine output is not improved, then a continuous diuretic infusion may be considered. To increase renal cortical blood flow, many clinicians administer dopamine (2–3?µg/kg/min) in conjunction with diuretic therapy, although there are no controlled data to support this practice.

If there is no response to a diuretic challenge, diuretics should be discontinued and fluid restriction becomes essential. Patients with a relatively normal intravascular volume should initially be limited to 400?mL/m^2 /24?hr (insensible losses) plus an amount of fluid equal to the urine output for that day. Extrarenal (blood, gastrointestinal tract) fluid losses should be replaced, milliliter for milliliter, with appropriate fluids. On the other hand, markedly hypervolemic patients may require further fluid restriction, omitting the replacement of insensible fluid losses, urine output, and extrarenal losses to diminish the expanded intravascular volume. In general, glucose-containing solutions (10–30%) without electrolytes are used as maintenance fluids and the composition of the fluid modified according to the state of electrolyte balance. Fluid intake, urine and stool output, body weight, and serum chemistries should be monitored on a daily basis.

In ARF, rapid development of *hyperkalemia* (serum potassium level > 6?mEq/L) may lead to cardiac arrhythmia, cardiac arrest, and death. The earliest electrocardiographic change seen in patients with developing hyperkalemia is the appearance of peaked T waves. This may be followed by widening of the QRS intervals, ST segment depression, ventricular arrhythmias, and cardiac arrest.

Procedures to deplete body potassium should be initiated when the serum potassium value rises to 6.0?mEq/L. Exogenous sources of potassium (dietary, intravenous fluids, total parenteral nutrition) should be eliminated.

Sodium polystyrene sulfonate resin (Kayexalate®), 1?g/kg, should be given orally or by retention enema. This resin exchanges sodium for potassium and may take several hours to take effect. A single dose of 1?g/kg can be expected to lower the serum potassium level by about 1?mEq/L. Resin therapy may be repeated every 2?hr, the frequency being limited primarily by the risk of sodium overload.

More severe elevations in serum potassium (>7?mEq/L), especially if accompanied by electrocardiographic changes, require emergency measures in addition to Kayexalate®. The following agents should be administered:

1. Calcium gluconate 10% solution, 1.0?mL/kg IV, over 3–5 min
2. Sodium bicarbonate, 1–2?mEq/kg IV over 5–10 min
3. Regular insulin, 0.1 U/kg, with glucose 50% solution, 1?mL/kg, over 1?hr

Calcium gluconate counteracts the potassium-induced increase in myocardial irritability but does not lower the serum potassium level. Administration of sodium bicarbonate and insulin and glucose lowers the serum potassium level by shifting potassium from the extracellular to the intracellular compartment. Because the

duration of action of these emergency measures is just a few hours, persistent hyperkalemia should be managed by dialysis.

Mild *metabolic acidosis* is common in ARF as a result of retention of hydrogen ions, phosphate, and sulfate, but it rarely requires treatment. If acidosis is severe (arterial pH < 7.15; serum bicarbonate < 8?mEq/L) or contributes to hyperkalemia, treatment is required. The acidosis should be corrected partially by the intravenous route, generally giving enough bicarbonate to raise the arterial pH to 7.20 (which approximates a serum bicarbonate level of 12?mEq/L). The remainder of the correction may be accomplished by oral administration of sodium bicarbonate after normalization of the serum calcium and phosphorus levels. Correction of metabolic acidosis with intravenous bicarbonate may precipitate tetany in patients with renal failure as rapid correction of acidosis reduces the ionized calcium concentration (see also Chapter 48.9).

Hypocalcemia is primarily treated by lowering the serum phosphorus level. Calcium should not be given intravenously, except in cases of tetany, to avoid deposition of calcium salts into tissues. Patients should be instructed to follow a low phosphorus diet, and phosphate binders should be given by mouth to bind any ingested phosphate and increase gastrointestinal phosphate excretion. Common agents include calcium carbonate (Tums tablets or Titralac suspension), calcium acetate (PhosLo), and sevelamer (Renagel). The starting dose is one to three tablets with meals. The total daily dose should be gradually increased until the serum phosphorus level falls to normal. Aluminum-based binders, which were commonly employed in the past, should be avoided because of the possibility of aluminum toxicity.

Hyponatremia is most commonly a dilutional disturbance, which must be corrected by fluid restriction rather than sodium chloride administration. Administration of hypertonic (3%) saline should be limited to those patients with symptomatic hyponatremia (seizures, lethargy) or those with serum sodium

level less than 120?mEq/L. Acute correction of the serum sodium to 125?mEq/L (mmol/L) should be accomplished using the following formula:

ARF patients are predisposed to *gastrointestinal bleeding* because of uremic platelet dysfunction, increased stress, and heparin exposure if on hemodialysis or continuous renal replacement therapy. Oral or intravenous H_2 blockers such as ranitidine are commonly administered to prevent this complication.

Hypertension may result from hyperreninemia associated with the primary disease process and/or expansion of the extracellular fluid volume and is most common in ARF patients with acute glomerulonephritis or HUS. Salt and water restriction is critical, and diuretic administration may be useful (see Chapter 437). Isradipine (0.05–0.15?mg/kg/dose, maximum dose 5?mg qid) or nifedipine (0.25–0.5?mg/kg PO, maximum dose 10?mg q 2–6?hr) may be administered for relatively rapid reduction in blood pressure. Longer-acting agents such as calcium channel blockers (amlodipine, 0.1–0.6?mg/kg/24?hr qd or bid), ß-blockers (propranolol, 0.5–8?mg/kg/24?hr divided bid-tid; labetalol, 4–40?mg/kg/24?hr divided bid-tid) may be helpful in maintaining control of blood pressure. Children with severe symptomatic hypertension (hypertensive urgency/emergency) should be treated with continuous infusions of sodium nitroprusside (0.5–10?µg/kg/min), labetalol (0.25–3.0?mg/kg/hr), or esmolol (150–300?µg/kg/min) and converted to intermittently dosed antihypertensives when more stable.

Neurologic symptoms in ARF may include headache, seizures, lethargy, and confusion. Potential etiologic factors include hyponatremia, hypocalcemia, hypertension, cerebral hemorrhage, cerebral vasculitis, and the uremic state. Diazepam is the most effective agent in controlling seizures, and therapy should be directed toward the precipitating cause.

The *anemia* of ARF is generally mild (hemoglobin 9–10?g/dL) and primarily results from volume expansion (hemodilution). However, children with HUS, SLE, active bleeding, or prolonged ARF may require transfusion of packed red blood cells if their hemoglobin level falls below 7?g/dL. In hypervolemic patients, blood transfusion carries the risk of further volume expansion, which may precipitate hypertension, heart failure, and pulmonary edema. Slow (4–6?hr) transfusion with packed red blood cells (10?mL/kg) diminishes the risk of hypervolemia. The use of fresh, washed red blood cells minimizes the risk of hyperkalemia. In the presence of severe hypervolemia or hyperkalemia, blood transfusions are most safely administered during dialysis/ultrafiltration.

Nutrition is of critical importance in children who develop ARF. In most cases, sodium, potassium, and phosphorus should be restricted. Protein intake should be restricted moderately while maximizing caloric intake to minimize the accumulation of nitrogenous wastes. In critically ill patients with ARF, parenteral hyperalimentation with essential amino acids should be considered.

DIALYSIS.

Indications for dialysis in ARF include the following:

1. Volume overload with evidence of hypertension and/or pulmonary edema refractory to diuretic therapy
2. Persistent hyperkalemia
3. Severe metabolic acidosis unresponsive to medical management
4. Neurologic symptoms (altered mental status, seizures)
5. Blood urea nitrogen greater than 100–150?mg/dL (or lower if rapidly rising)
6. Calcium/phosphorus imbalance, with hypocalcemic tetany

An additional indication for dialysis is the inability to provide adequate nutritional intake because of the need for severe fluid restriction. In patients with ARF, dialysis support may be necessary for days or for up to 12 wk. Many patients with ARF require dialysis support for 1–3 wk. The advantages and disadvantages of the three types of dialysis currently available are shown in Table 527–2 .

Intermittent hemodialysis is useful in patients with relatively stable hemodynamic status. This highly efficient process accomplishes both fluid and electrolyte removal

in 3–4?hr sessions using a pump-driven extracorporeal circuit and large central venous catheter. Intermittent hemodialysis may be performed three to seven times a week based on the patient's fluid and electrolyte balance.

Peritoneal dialysis is most commonly employed in neonates and infants with ARF, although this modality may be used in children and adolescents of all ages. Hyperosmolar dialysate is infused into the peritoneal cavity via a surgically or percutaneously placed peritoneal dialysis catheter. The fluid is allowed to dwell for 45–60?min and is then drained from the patient by gravity (manually or with the use of a cycler machine), accomplishing both fluid and electrolyte removal. Cycles are repeated for 8–24?hr/day based on the patient's fluid and electrolyte balance.

Anticoagulation is not necessary; peritoneal dialysis is contraindicated in patients with abdominal disorders.

Continuous renal replacement therapy (CRRT) is useful in patients with unstable hemodynamic status, concomitant sepsis, or multiorgan failure in the intensive care setting. CRRT is an extracorporeal therapy in which fluid, electrolytes, and small-and medium-sized solutes are continuously removed from the blood (24?hr/day) using a specialized pump-driven machine. Usually, a double-lumen catheter is placed into the subclavian, internal jugular, or femoral vein. The patient is then connected to the pump-driven CRRT circuit, which continuously passes the patient's blood across a highly permeable filter.

CRRT may be performed in three basic fashions. In continuous venovenous hemofiltration (CVVH), a large amount of fluid moves by pressure across the filter, bringing with it by convection other molecules such as urea, creatinine, phosphorus, and uric acid. The blood volume is reconstituted by intravenous infusion of a replacement fluid having a desirable electrolyte composition similar to the blood. Continuous venovenous dialysis

(CVVH-D) utilizes the principle of diffusion by circulating dialysate in a countercurrent direction on the ultrafiltrate side of the membrane. No replacement fluid is used. Continuous hemodiafiltration (CVVH-DF) employs both replacement fluid and dialysate, offering the most effective solute removal of all forms of CRRT.

Prognosis.

The mortality rate in children with ARF is variable and depends entirely on the nature of the underlying disease process rather than on the renal failure itself. In general, children with ARF caused by a renal-limited condition such as postinfectious glomerulonephritis have a very low mortality rate (<1%); those with ARF related to multiorgan failure have a very high mortality rate (>90%).

The prognosis for recovery of renal function depends on the disorder that precipitated the ARF. In general, recovery of function is likely after ARF resulting from prerenal causes, HUS, ATN, acute interstitial nephritis, or tumor lysis syndrome. On the other hand, recovery of renal function is unusual when ARF results from most types of rapidly progressive glomerulonephritis, bilateral renal vein thrombosis, or bilateral cortical necrosis.

Medical management may be necessary for a prolonged period of time to treat sequelae of ARF, including chronic renal insufficiency, hypertension, renal tubular acidosis, and urinary concentrating defect.

527.2 Chronic Renal Failure

Chronic renal failure (CRF) is defined as an irreversible reduction in GFR. The prevalence of CRF in the pediatric population is approximately 18 per 1 million. The prognosis for the infant, child, or adolescent with CRF has improved dramatically over the past 4 decades because of improvements in medical management (aggressive nutritional support, recombinant erythropoietin, and recombinant growth hormone), dialysis techniques, and renal transplantation.

Etiology.

In children, CRF may be the result of congenital, acquired, inherited, or metabolic renal disease, and the underlying cause correlates closely with the age of the patient at the time when the CRF is first detected. CRF in children younger than 5 yr is most commonly a result of congenital abnormalities such as renal hypoplasia, dysplasia, and/or obstructive uropathy.

After 5 yr of age, acquired diseases (various forms of glomerulonephritis) and inherited disorders (familial juvenile nephronophthisis, Alport syndrome) predominate. CRF related to metabolic disorders (cystinosis, hyperoxaluria) and certain inherited disorders (polycystic kidney disease) may present throughout the childhood years.

Pathogenesis.

In addition to progressive injury with ongoing structural/metabolic genetic diseases, renal injury may progress despite removal of the original insult. Although the precise mechanisms that result in progressive deterioration of renal function are unclear, putative factors include hyperfiltration injury, persistent proteinuria, systemic or intrarenal hypertension, renal calcium-phosphorus deposition, and hyperlipidemia.

Hyperfiltration injury is proposed to be an important final common pathway of glomerular destruction, independent of the underlying cause of renal injury. As nephrons are lost, the remaining nephrons undergo structural and functional hypertrophy characterized by an increase in glomerular blood flow. The driving force for glomerular filtration is thereby increased in the surviving nephrons. Although this compensatory hyperfiltration temporarily preserves total renal function, it is theorized to cause progressive damage to the surviving glomeruli, possibly by a direct effect of the elevated hydrostatic pressure on the integrity of the capillary wall and/or the toxic effect of increased protein traffic across the capillary wall. Over time, as the population of sclerosed nephrons increases, the surviving nephrons suffer an increased excretory burden, resulting in a vicious cycle of increasing glomerular blood flow and hyperfiltration injury.

In addition to hyperfiltration injury, other factors may play a role in the progression of chronic renal insufficiency. Proteinuria itself may contribute to renal functional decline, as evidenced by studies that have shown a beneficial effect of reduction in proteinuria. Proteins that traverse the glomerular capillary wall may exert a direct toxic effect and recruit monocytes/macrophages, enhancing the process of glomerular sclerosis and tubulointerstitial fibrosis. Uncontrolled hypertension may exacerbate disease progression by causing arteriolar nephrosclerosis as well as by increasing the hyperfiltration injury described earlier.

Hyperphosphatemia may increase progression of disease by leading to calcium-phosphate deposition in the renal interstitium and blood vessels. Finally, hyperlipidemia, a common condition in CRF patients, may adversely affect glomerular function through oxidant-mediated injury.

CRF may be viewed as a continuum of disease with increasing biochemical and clinical manifestations as renal function deteriorates. The pathophysiologic manifestations of CRF are outlined in Table 527–3 . Although the terminology used to describe the degrees of renal dysfunction varies, many clinicians use the following definitions:

Mild chronic renal insufficiency: GFR 50–75?mL/min/l.73?m^2

Moderate chronic renal insufficiency: GFR 25–50?mL/min/l.73?m^2

Chronic renal failure (CRF): GFR 10–25?mL/min/l.73?m^2

End stage renal disease (ESRD): GFR < 10?mL/min/l.73?m^2

Clinical Manifestations.

The clinical presentation of CRF is quite varied and dependent on the underlying renal disease. Children and adolescents with CRF from glomerulonephritis, including the nephrotic syndrome, may present with edema, hypertension, hematuria, and proteinuria. Infants and children with congenital disorders such as renal dysplasia and obstructive uropathy may present in the neonatal period with failure to thrive, dehydration, urinary tract infection, or overt renal insufficiency. With the widespread use of prenatal ultrasonography, many of these infants are identified prenatally, allowing early diagnostic and therapeutic intervention. Children with familial juvenile nephronophthisis may have a very subtle presentation with nonspecific complaints such as headache, fatigue, lethargy, anorexia, vomiting, polydipsia, polyuria, and growth failure over a number of years.

The physical examination in patients with CRF may reveal pallor and a sallow appearance. Patients with long-standing

TABLE 527.2-3 -- **Pathophysiology of Chronic Renal Failure**

Manifestation	Mechanisms
Accumulation of nitrogenous waste products	Decrease in glomerular filtration rate
Acidosis	Decreased ammonia synthesis Impaired bicarbonate reabsorption Decreased net acid excretion
Sodium retention	Excessive renin production Oliguria
Sodium wasting	Solute diuresis Tubular damage
Urinary concentrating defect	Solute diuresis Tubular damage
Hyperkalemia	Decrease in glomerular filtration rate Metabolic acidosis Excessive potassium intake Hyporeninemic hypoaldosteronism
Renal osteodystrophy	Impaired renal production of 1,25-dihydroxycholecalciferol Hyperphosphatemia Hypocalcemia Secondary hyperparathyroidism
Growth retardation	Inadequate caloric intake Renal osteodystrophy Metabolic acidosis Anemia Growth hormone resistance
Anemia	Decreased erythropoietin production Iron deficiency Folate deficiency Vitamin B_{12} deficiency Decreased erythrocyte survival
Bleeding tendency	Defective platelet function
Infection	Defective granulocyte function Impaired cellular immune functions Indwelling dialysis catheters
Neurologic symptoms (fatigue, poor concentration, headache, drowsiness, memory loss, seizures, peripheral neuropathy)	Uremic factor(s) Aluminum toxicity Hypertension
Gastrointestinal symptoms (feeding intolerance, abdominal pain)	Gastroesophageal reflux Decreased gastrointestinal motility
Hypertension	Volume overload Excessive renin production
Hyperlipidemia	Decreased plasma lipoprotein lipase activity
Pericarditis/cardiomyopathy	Uremic factor(s) Hypertension Fluid overload

Glucose intolerance	Tissue insulin resistance

untreated CRF may have short stature and the bony abnormalities of renal osteodystrophy (see also Chapters 521.3 and 521.5). Children with CRF due to glomerulonephritis (or children with advanced renal failure from any cause) may have edema, hypertension, and other signs of extracellular fluid volume overload.

Laboratory findings include elevations in blood urea nitrogen and serum creatinine. The degree of renal dysfunction may be determined by applying the following formula, which provides an estimation of the patient's GFR:

where k is 0.33 for low-birthweight infants younger than 1?yr, 0.45 for term AGA infants younger than 1?yr, 0.55 for children and adolescent females, and 0.70 for adolescent males.

Laboratory findings may also reveal hyperkalemia, hyponatremia (if volume overloaded), acidosis, hypocalcemia, hyperphosphatemia, and an elevation in uric acid. Patients with heavy proteinuria may have hypoalbuminemia. A complete blood cell count usually shows a normochromic, normocytic anemia. Serum cholesterol and triglyceride levels are usually elevated. In children with CRF caused by glomerulonephritis, the urinalysis shows hematuria and proteinuria. In children with CRF from congenital lesions such as renal dysplasia, the urinalysis usually has a low specific gravity and minimal abnormalities.

Treatment.

The treatment of CRF is aimed at (1) replacing absent/ diminished renal functions, which progressively increase in parallel with the progressive loss of GFR, and (2) slowing the progression of renal dysfunction. Children with CRF should be treated at a medical center capable of supplying multidisciplinary services, including medical, nursing, social service, nutritional, and psychological support.

The management of CRF requires close monitoring of a patient's clinical and laboratory status. Blood studies to be followed routinely include the hemoglobin level and serum electrolytes, blood urea nitrogen, creatinine, calcium, phosphorus, albumin, and alkaline phosphatase. Periodic measurement of intact parathyroid hormone (PTH) levels and roentgenographic studies of bone may be of value in detecting early evidence of renal osteodystrophy. Echocardiography should be performed

periodically to identify left ventricular hypertrophy and cardiac dysfunction that may occur as a consequence of the complications of CRF.

FLUID AND ELECTROLYTE MANAGEMENT.

Most children with chronic renal insufficiency maintain normal sodium and water balance with the sodium intake derived from an appropriate diet. However, infants and children whose renal failure is a consequence of renal dysplasia may be polyuric with significant urinary sodium losses. These children may benefit from high volume, low caloric density feedings with sodium supplementation. On the other hand, children with high blood pressure, edema, or heart failure may require sodium restriction and diuretic therapy. Fluid restriction is rarely necessary in children with CRF until the development of end-stage renal disease (ESRD) requires the initiation of dialysis.

In most children with CRF, potassium balance is maintained until renal function deteriorates to the level at which dialysis is initiated. Hyperkalemia may develop, however, in patients with moderate renal insufficiency who have excessive dietary potassium intake, severe acidosis, or hyporeninemic hypoaldosteronism (related to destruction of the renin-secreting juxtaglomerular apparatus). Hyperkalemia may be treated by restriction of dietary potassium intake, administration of oral alkalinizing agents, and/or treatment with Kayexalate.

ACIDOSIS.

Metabolic acidosis develops in almost all children with CRF owing to decreased net acid excretion by the failing kidneys. Either Bicitra (1?mEq sodium citrate/mL) or sodium bicarbonate tablets (650?mg equals 8?mEq of base) may be used to maintain the serum bicarbonate level above 22?mEq/L.

NUTRITION.

Patients with CRF usually require progressive restriction of various dietary components as their renal function declines. Dietary phosphorus, potassium, and sodium should be restricted according to the individual patient's laboratory studies and fluid balance. In infants with CRF, formulas containing a reduced amount of phosphate (Similac PM 60/40) are commonly employed.

The optimal caloric intake in patients with CRF is unknown, but it is recommended to provide at least the recommended dietary allowance of caloric intake for age. Protein intake should be 2.5?g/kg/24?hr and should consist of proteins of high biologic value that are metabolized primarily to usable amino acids rather than to nitrogenous wastes. The proteins of highest biologic value are those of eggs and milk, followed by meat, fish, and fowl.

Dietary intake should be adjusted according to response, optimally through consultation with a dietitian with expertise in childhood renal failure. Caloric intake may be enhanced in infants by supplementing the formula with modular components of carbohydrates (Polycose), fat (medium chain triglycerides [MCT] oil), and protein (pro-Mod) as tolerated by the patient. In older children and adolescents, commercial enteral products (Boost) may be helpful. If oral caloric intake remains inadequate and/or weight gain and growth velocity suboptimal, enteral tube feedings should be considered. Supplemental feedings may be provided via nasogastric, gastrostomy, or gastrojejunal tube. Continuous overnight infusions with or without daytime bolus administrations are commonly employed.

Children with CRF may become deficient in water-soluble vitamins either because of inadequate dietary intake or dialysis losses. These should be routinely supplied,

using preparations such as Nephrocaps (Fleming, Fenton, MO). Zinc and iron supplements should be added only if deficiencies are confirmed. Supplementation with fat-soluble vitamins A, E, and K is usually not required.

GROWTH.

Short stature has emerged as one of the most significant long-term sequelae of childhood CRF. A key etiologic factor is that children with CRF have an apparent growth hormone (GH)–resistant state with elevated GH levels but decreased insulin-like growth factor-I (IGF-I) levels and major abnormalities of IGF-binding proteins.

Children with CRF who remain less than -2 SD for height despite optimal medical support (adequate caloric intake and effective treatment of renal osteodystrophy, anemia, and metabolic acidosis) may benefit from treatment with pharmacologic doses of recombinant human growth hormone (rHuGH). Treatment may be initiated with rHuGH (0.05?mg/kg/24?hr) subcutaneously, with periodic adjustment in the dose to achieve a goal of normal height velocity for age.

Treatment with rHuGH may be continued until the patient (1) reaches the 50th percentile for midparental height, (2) achieves a final adult height, or (3) undergoes renal transplantation. Long-term rHuGH treatment significantly improves final adult height and induces persistent catch-up growth, and the majority of patients achieve a normal adult height.

RENAL OSTEODYSTROPHY.

The term *renal osteodystrophy* is used to indicate a spectrum of bone disorders seen in patients with CRF. The most common condition seen in children is high-turnover bone disease caused by secondary hyperparathyroidism. The skeletal pathologic finding in this condition is osteitis fibrosa cystica.

The pathophysiology of renal osteodystrophy is complex. Early in the course of CRF, when the GFR declines to approximately 50% of normal, the decrease in functional renal mass leads to a decline in renal 1a-hydroxylase activity, with decreased production of activated vitamin D (1,25- dihydroxycholecalciferol). This deficiency in activated vitamin D results in decreased intestinal calcium absorption, hypocalcemia, and increased parathyroid gland activity. Excessive PTH secretion attempts to correct the hypocalcemia by effecting an increase in bone resorption. Later in the course of CRF, when the GFR declines to 20–25% of normal, compensatory mechanisms to enhance phosphate excretion become inadequate, resulting in hyperphosphatemia, which further promotes hypocalcemia and increased PTH secretion.

Clinical manifestations of renal osteodystrophy include muscle weakness, bone pain, and fractures with minor trauma. In growing children, rachitic changes, varus and valgus deformities of the long bones, and slipped capital femoral epiphyses may be seen. Laboratory studies may demonstrate a decreased serum calcium level, increased serum phosphorus level, increased alkaline phosphatase, and a normal PTH level. Radiographs of the hands, wrists, and knees show subperiosteal resorption of bone with widening of the metaphyses.

The goals of *treatment* are to prevent bony deformity and normalize growth velocity using both dietary and pharmacologic interventions. Children and adolescents should follow a low phosphorus diet, and infants should be provided with a low- phosphorus formula such as Similac PM 60/40. Because it is impossible to fully restrict phosphorus intake, phosphate binders are used to enhance fecal phosphate excretion. Calcium carbonate (Tums) and calcium acetate (PhosLo) are the most commonly used phosphate binders, although newer, non–calcium-based binders such as sevelamer (Renagel) are increasing in use, particularly in patients prone to hypercalcemia.

Because aluminum may be absorbed from the gastrointestinal tract and can lead to aluminum toxicity, aluminum-based binders should be avoided.

The cornerstone of therapy for renal osteodystrophy is vitamin D administration. Vitamin D therapy is indicated in patients with (1) renal osteodystrophy with PTH levels greater than three times the upper limit of normal or (2) persistent hypocalcemia despite reduction of the serum phosphorus level below 6?mg/dL. Therapy may be initiated with 0.01–0.05?µg/kg/24?hr of calcitriol (Rocaltrol, 0.25-µg capsules or 1?µg/mL suspension). Rarely, dihydrotachysterol (DHT) solution (0.05–0.20?mg/ 24?hr) may be used. Newer noncalcemic vitamin D analogues such as paracalcitol and doxercalciferol are increasingly used, especially in patients predisposed to hypercalcemia. Phosphate binders and vitamin D should be adjusted to maintain the intact

---

PTH level two to three times the upper limit of normal and the serum calcium and phosphorus levels within the normal range for age. Many nephrologists also attempt to maintain the calcium/phosphorus product ($Ca \times PO_4$) less than 55 to minimize the possibility of tissue deposition of calcium phosphorus salts.

ADYNAMIC BONE DISEASE.

Adynamic bone disease (low-turnover bone disease) has been increasingly recognized in both children and adults with CRF. The pathologic finding in this condition is osteomalacia. This condition has been associated with oversuppression of PTH, perhaps related to the widespread use of calcium-containing phosphate binders and vitamin D analogues.

ANEMIA.

Anemia in patients with CRF is primarily the result of inadequate erythropoietin production by the failing kidneys and usually becomes manifest at a GFR less than 35?mL/min/1.73?m^2

Other possible contributory factors include iron deficiency, folic acid or vitamin B_{12}

deficiency,_and decreased erythrocyte survival. Whereas patients with CRF often required repeated red cell transfusions in the past, the introduction of recombinant human erythropoietin (rHuEPO) therapy has dramatically decreased the need for transfusion in patients with CRF. Erythropoietin is usually initiated when the patient's hemoglobin concentration falls below 10?g/dL, at a dose of 50–150?mg/kg/dose subcutaneously one to three times weekly. The dose is adjusted to maintain the hemoglobin concentration between 11–12?g/dL. All patients receiving rHuEPO therapy should be provided with either oral or intravenous iron supplementation. Patients who appear to be resistant to rHuEPO should be evaluated for iron deficiency, occult blood loss, chronic infection/inflammatory state, vitamin B_{12} or folate deficiency, and bone marrow fibrosis related to secondary hyperparathyroidism. The merits of erythropoietin therapy are summarized in Box 527–2 .

HYPERTENSION.

Children with CRF may have sustained hypertension related to volume overload and/or excessive renin production related to glomerular disease. Hypertensive children with suspected volume overload should follow a salt-restricted diet (2–3?g/24?hr) and may benefit from loop diuretic (furosemide) therapy. Angiotensin-converting enzyme (ACE) inhibitors (enalapril, lisinopril) are the antihypertensive medication of choice in all children with proteinuric renal disease, because of their potential ability to slow the progression to end-stage renal disease. Angiotensin-II blockers (losartan) have been shown to be effective in controlling blood pressure and in slowing disease progression in patients with diabetic nephropathy. Extreme care must be taken when using these agents, however, to monitor renal function and electrolyte balance, particularly in those children with advanced CRF. Calcium channel blockers (amlodipine, nifedipine), centrally acting agents (clonidine), and ß-blockers (propranolol, atenolol) may be useful in children

Box 527.2-2. Merits of Recombinant Human Erythropoietin Therapy

BENEFITS

- Avoidance/minimization of blood transfusions
  - Reduced sensitization to histocompatibility antigens
  - Reduced exposure to infectious diseases
  - Less chance of chronic iron overload
- Improved appetite
- Enhanced exercise tolerance
- Improved sleep
- Improved well-being

POTENTIAL COMPLICATIONS

- Iron deficiency
- Hypertension
- Seizures
- Clotting of vascular access
- Pure red cell aplasia (in adults due to rHuEPO anibodies)

with CRF whose blood pressure cannot be controlled using dietary sodium restriction, diuretics, and ACE inhibitors.

IMMUNIZATIONS.

Children with CRF should receive all standard immunizations according to the schedule used for healthy children. An exception must be made in withholding live vaccines from children with CRF related to glomerulonephritis during treatment with

immunosuppressive medications. It is critical, however, to make every attempt to administer live virus vaccines (MMR, varicella) before renal transplantation, because these vaccines are not advised for use in immunosuppressed patients. All children with CRF should receive a yearly influenza vaccine.

Data suggest that children with CRF may respond suboptimally to immunizations.

ADJUSTMENT IN DRUG DOSAGE.

Because many drugs are excreted by the kidneys, their dosing may need to be adjusted in patients with chronic renal insufficiency to maximize effectiveness and minimize the risk of toxicity (see Chapter 712). Strategies in dose adjustment include lengthening of the interval between doses, decreasing the absolute dose, or both.

PROGRESSION OF DISEASE.

Although there are no definitive treatments to improve renal function in children or adults with CRF, there are several strategies that may be effective in slowing the rate of progression of renal dysfunction. Optimal control of hypertension (maintaining the blood pressure less than the 75th percentile) is critical in all patients with CRF. ACE inhibitors or angiotensin-II blockers should be the antihypertensive drug of choice in hypertensive children with chronic proteinuric renal disease. Such agents should also be strongly considered in children with CRF who have significant proteinuria, even in the absence of hypertension. Serum phosphorus should be maintained within the normal range for age and the calcium-phosphorus product less than 55 to minimize renal calcium-phosphorus deposition. Prompt treatment of infectious complications and episodes of dehydration may minimize additional loss of renal parenchyma.

Other potentially beneficial recommendations include correction of anemia with erythropoietin therapy, avoidance of cigarette smoking, minimization of regular use of nonsteroidal anti-inflammatory medications, and control of hyperlipidemia. Although dietary protein restriction has been shown to be useful in adults, this recommendation is generally not suggested for children with CRF because of the concern of adverse effects on growth and development.

527.3 End-Stage Renal Disease

End-stage renal disease (ESRD) represents the state in which a patient's renal dysfunction has progressed to the point at which homeostasis and survival can no longer be sustained with native kidney function and maximal medical management. At this point, renal replacement therapy (dialysis or renal transplantation) becomes necessary. The ultimate goal for children with ESRD is successful kidney transplantation (see Chapter 528) because it provides the most normal lifestyle and possibility for rehabilitation for the child and family. Seventy-five percent of North American children with ESRD, however, require a period of dialysis before transplantation can be performed.

The optimal time to initiate dialysis is based on a combination of the biochemical and clinical characteristics of the patient. It is the consensus opinion to arrange renal replacement therapy when the child's native kidney function falls to a GFR (measured by creatinine clearance) of 10–15?mL/min/1.73?m^2 . Other specific indications include refractory fluid overload, electrolyte imbalance, acidosis, growth failure, or uremic symptoms, including fatigue, nausea, and impaired school performance. Cardiovascular death accounts for about a quarter of pediatric and young adult ESRD deaths. In general, most nephrologists

attempt to initiate dialysis early enough to prevent the development of severe fluid and electrolyte abnormalities, malnutrition, and uremic symptoms.

The selection of dialysis modality must be individualized to fit the needs of each child. In the North America, two thirds of children with ESRD are treated with peritoneal dialysis, whereas one third are treated with hemodialysis. Age is a defining factor in dialysis modality selection: 88% of infants and children from birth to 5 yr of age are treated with peritoneal dialysis, whereas 54% of children older than 12 yr of age are treated with hemodialysis.

Peritoneal dialysis is a technique that employs the patient's peritoneal membrane as a dialyzer. Excess body water is removed by an osmotic gradient created by the high dextrose concentration in the dialysate; wastes are removed by diffusion from the peritoneal capillaries into the dialysate. Access to the peritoneal cavity is achieved by a surgically inserted, tunneled Tenckhoff catheter.

Peritoneal dialysis may be provided either as continuous ambulatory peritoneal dialysis (CAPD) or as any of several forms of automated therapies using a cycler (continuous cyclic peritoneal dialysis [CCPD], intermittent peritoneal dialysis [IPD], or nocturnal intermittent peritoneal dialysis [NIPD]). The majority of North American children treated with peritoneal dialysis use cycler-driven therapy, which allows the child and family to be free of dialysis demands during the waking hours. The exchanges are performed automatically during sleep by machine. This permits an uninterrupted day of activities, a reduction in the number of dialysis catheter connections and disconnections (which should decrease the risk of peritonitis), and a reduction in the time required by patients and parents to perform dialysis, reducing the risk of fatigue and burnout. Because peritoneal dialysis is not as efficient as hemodialysis, it must be performed on a daily basis rather than 3 times weekly as in hemodialysis. The merits of peritoneal dialysis are outlined in Box 527–3 .

Hemodialysis, unlike peritoneal dialysis, is usually performed in a hospital setting. Children and adolescents typically have three 3–4 hour sessions per week during which fluid and solute wastes are removed. Access to the child's circulation is achieved by a surgically created arteriovenous fistula, graft, or indwelling subclavian or internal jugular catheter.

Box 527.3-3. Merits of Peritoneal Dialysis in Pediatric Patients with End-Stage Renal Disease

ADVANTAGES

- Ability to perform dialysis treatment at home
- Technically easier than hemodialysis, especially in infants
- Ability to live a greater distance from medical center
- Freedom to attend school and after-school activities
- Less restrictive diet
- Less expensive than hemodialysis

DISADVANTAGES

- Catheter malfunction
- Catheter-related infections (peritonitis, exit-site)
- Impaired appetite (due to full peritoneal cavity)
- Negative body image
- Caregiver "burnout"

Chapter 528 - Renal Transplantation

Rodrigo E. Urizar

Long-term dialysis therapy for end-stage renal disease (ESRD) is frequently associated with failure to thrive, social maladaptation, lack of sexual maturation, and chronic encephalopathy (in the very young) and explains the reluctance to dialyze children extensively unless more acceptable alternatives are unavailable. Optimal treatment for children with ESRD is early renal transplantation (RT) from a living related donor (LRD-RT). Although less successful than LRD-RT, cadaveric (CAD) grafts are also used in children.

Epidemiology.

The United States Renal Data System (USRDS) documents 20 new ESRD cases per million children each year, peaking at about age 11–15 yr. Before 1 yr of age, the incidence is 0.2 patient/million per year. The North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) reported the registration and sequential follow-up, through January 2001, of over 80% of American and Canadian children with chronic renal insufficiency (CRI), dialysis (D), transplantation, and post-transplant events. Of 11,973 registered children, 6,878, or 57.44%, received their first (index) transplant, whereas 667 additional cases (of 7,545 transplants, 63%) represented repeated procedures in the same patient, a cumulative effect since NAPRTCS's inception in 1987. Of the remaining patients, 3,271 had CRI (27.3%), whereas 1,340 (11.2%) of the 11,973 were on dialysis, all candidates for RT in the future. An estimated 43–45% of 2,000 pediatric RTs performed in the United States used kidneys donated by parents (37%) and by siblings or other relatives (6%). Preemptive RT (carried out without previous dialysis) constitutes 22% of LRD engraftings. Indications for RT are noted in Box 528–1 .

Box 528-1. Criteria for Performing Living Related Donor or Cadaveric Renal Transplantation in Pediatric Patients

Renal failure, chronic or end-stage renal disease of any etiology

Age, weight dependent to accommodate adult kidney

Good nutritional condition

Absence of

- Active infection
- Severe mental retardation
- Obstructed urinary tract (ileal loops, colonic diversions and bladder augmentation procedures are helpful in many instances)
- Gastrointestinal, liver, pancreas, or cardiovascular disease
- Serious psychosocial or behavioral problems, and noncompliance with medication and dietary regimen
- Sensitization in recipient
- Massive obesity

From Mauer SM, Nevins TE, Ascher N: Renal transplantation in children. In Edelman CM Jr (editor): Pediatric Kidney Disease. Boston, Little, Brown & Company, 1992, pp 941–81.

A well-functioning graft (LRD or CAD) may fully rehabilitate the patient. Nonetheless, the expectant graft recipient and relatives must understand that RT is not a permanent cure for ESRD. Furthermore, a poorly functioning transplanted kidney (uncontrollable progressive rejection) is associated with serious morbidity, mortality, and prospective return to long-term dialysis or initiation of it. The transiency of renal grafts has committed transplant programs to many engraftments per patient, a goal seriously hampered by the limited availability of CAD kidneys. The latter may reflect reticence of the lay and professional community (general public, nurses, physicians) toward organ donation. Because of the large disproportion among the yearly increments in the need for RT (22%), and the number of transplants performed in the same period (8%), it is estimated that one hundred thousand kidneys will be required to be distributed among 180,000 patients on dialysis in the United States. In the present state of organ procurement, this objective cannot be met. Interim measures (i.e., optimizing living related and nonrelated, and cadaveric renal donation efforts, including kidneys obtained from children younger than 15 yr of age who have suffered brain death) and attempts at xenotransplantation (transplantation between different species) are being applied. Xenotransplants are presently only used on a purely experimental basis.

Causes of ESRD vary with the patient's age and include congenital renal diseases (53%), glomerulonephritides (20%), focal segmental glomerular sclerosis (12%), metabolic diseases (10%), and miscellaneous (5%) (Box 528–2 and Table 528–1). Although the glomerulopathies constitute a significant proportion of this population (particularly in 13–17 yr olds), congenital and obstructive processes predominate in the very young (<5 yr).

TABLE 528-1 -- **Individual Glomerulopathies of Childhood That May Progress to Chronic/End-Stage Renal Disease**

Entity	Clinical Manifestation
Idiopathic rapidly progressive GN (crescentic GN, mediated by immune complexes)	Acute progressive renal failure
IgA nephropathies (Berger disease, anaphylactoid or Henoch-Schönlein purpura)	Chronic active GN, nephrotic syndrome, occasionally RPGN
Membranoproliferative glomerulonephritis (idiopathic; types I, II, and III)	Acute and chronic nephritic syndrome, occasionally RPGN
Focal segmental glomerulosclerosis Systemic lupus GN (WHO types 3 & 4)	Nephrotic syndrome, progressive renal failure, acute/chronic active progressive GN, occasionally RPGN
Microangiopathic syndromes (hemolytic, uremic, and thrombotic thrombocytopenic purpura syndromes)	Acute, chronic, and occasionally RPGN
Vasculitis (polyarteritis nodosa and Wegener granulomatosis)	Same
Anti–basement membrane antibody diseases (Goodpasture syndrome and idiopathic RPGN)	Acute, progressive renal failure, and RPGN with or without pulmonary renal syndrome

GN = Glomerulonephritis; RPGN = rapidly progressive glomerulonephritis

Box 528-2. Most Frequent Hereditary-Metabolic Diseases of Childhood That Lead to End-Stage Renal Disease

Nephronophthisis—medullary cystic disease

Congenital nephrotic syndrome

Alport syndrome

Nephropathic and juvenile cystinosis

Primary oxalosis with oxaluria

Polycystic kidney disease (both infantile and adult varieties)

Nail-patella syndrome

Treatment.

Children weighing less than 15–20?kg have a transperitoneal graft via a midline incision; in those weighing more than 20?kg, the kidney is placed retroperitoneally in the right iliac fossa. Renal vessels are anastomosed to the recipient iliac vessels, and the ureter is reimplanted in the bladder (ureteroneocystostomy). The extraperitoneal kidney facilitates access for future percutaneous biopsies. The donor and recipient clinical laboratory evaluations before RT are summarized in Box 528–3 . Very young age of the recipient may be an obstacle to RT. For both LRD and CAD recipients, age younger than 24 mo is associated with decreased graft survival. Nevertheless, some institutions accept patients 5–6 mo old weighing 5–6?kg to be engrafted with adult kidneys. In addition, pediatric patients transplanted with small kidneys do not fare as well as expected. Specifically, for CAD recipients, donor age of less than 6 yr is associated with decreased graft survival.

Kidney grafts from LRD have significantly better survival than CAD-RT. Approximately 90% of kidneys from LRD function adequately by 1 yr and 80% function by the 3rd yr; the figures for CAD-RT are 72% and 65%, respectively. Generally, CAD-RT in children is less favorable than in adults. In transplant recipients who are younger than 1 yr, the 2-yr graft survival is less than that of older children. Overall, by 39 mo after RT, 80% of LRD and 58% of CAD-RT are functional.

Approximately 50% of graft failure is due to rejection. In 26%, rejection was acute, whereas in 7% recurrence of the original renal disease induced the transplant failure. Although almost any glomerulopathy may redevelop in the graft, focal segmental glomerulosclerosis is observed most frequently (see Table 528–2).

Thrombosis-related kidney failure occurs in 15% of cases. In patients with LRD-RT, thrombotic episodes developed in very young recipients, presumably because of hemodynamic and/or technical problems. Conversely, graft thrombosis in CAD-RT is unaffected by the recipient age but is proportional to the donor age. In older children, acute renal failure is frequently caused by tubular necrosis, which may contribute to graft loss. In summary, identified risks for graft loss in the pediatric population include recipient age younger than 2 yr, cadaveric donor less than 6 yr, previous renal transplantation, delayed graft function (acute tubular necrosis), and lack of antilymphocyte

Box 528-3. Clinical and Laboratory Evaluation of Prospective Living Related Kidney Donor and Recipient

RECIPIENT

Complete history and physical examination—updated immunizations, including pneumococcal and hepatitis B

Transplant orientation session: patient (if old enough), parents, prospective donors, transplant surgeon or representative, nephrologist or representative, social worker

Laboratory data

- Blood group (ABO)
- Tissue typing (HLA-A, -B, -C, -D/DR), MLC
- Hepatitis, cytomegalovirus, varicella, Epstein-Barr virus panel
- CBC, complement (C3, C4), ANA, quantitative Ig
- Serum creatinine, electrolytes, cholesterol, liver function tests, coagulation profile, blood sugar
- Urinalysis, urine and throat

Serum creatinine, electrolytes, cholesterol, liver function tests, coagulation profile, blood sugar

Urinalysis, urine and throat cultures

Chest radiograph (two-position), bone age films (if not previously available)

Neurologic consult and EEG and CT scan of brain (for infants)

Dental evaluation

Cultures: exit site of all catheters and peritoneal fluid in patients undergoing CAPD

Complete urologic evaluation for those with obstructive or congenital urinary tract problems

24-hr protein excretion

DONOR

Complete history and physical examination

Chest radiographs

Electrocardiogram

Renal ultrasonography (IVP if necessary)

Laboratory

CBC, ESR, ABO blood groups, HLA and MLC testing

Coagulation profile

Serum creatinine and electrolytes, liver function tests, blood sugar

Urinalysis, urine culture, 24-hr urine protein and creatinine excretion

Hepatitis, cytomegalovirus, herpes, Epstein-Barr virus antibody titers

Renal angiogram

EEG = electroencephalogram; CT = computed tomography; CAPD = continuous ambulatory peritoneal dialysis; IVP = intravenous pyelogram; CBC = complete blood cell count; ESR = erythrocyte sedimentation rate.
From Mauer SM, Nevins TE, Ascher N: Renal transplantation in children. In Edelman CM Jr (editor): Pediatric Kidney Disease. Boston, Little, Brown & Company, 1992, pp 941–81.

therapy with antithymocyte gamma globulin (ATGAM) or OKT3.

Histocompatibility.

The major histocompatibility complex (MHC) genes, present on the short arm of chromosome 6, encode the human leukocyte antigens (HLA) (Fig. 528–1). These are composed of class I proteins (tissue transplantation antigens) and cell-mediated immunotoxicity; class II proteins that control

Figure 528-1 Organization of HLA region of chromosome 6. The loci for HLA-A, -B, and -C are found in the class I region. The loci encoding HLA-DR, -DQ, and -DP are found in the class II region, centromeric to class I. In between classes I and II are the so-called class III genes, which encode some of the complement proteins as well as some cytokines. (From Grimm PC, Laufer J, Ettenger RB: The immunobiology of renal transplantation. In Edelman CM Jr [editor]: *Pediatric Kidney Disease.* Boston, Little, Brown & Company, 1992.)

induction of immune response; and class III proteins, which include tumor necrosis factor (TNF) and complement components (C2 and C4). Each chromosome 6 contains all three classes of proteins: HLA-A, -B, and -C for class I; HLA-DP, -DQ, and -DR for class II; and C2, C4, and TNF for class III. Multiple and co-dominant alleles (polymorphism) exist for each protein: 23(A), 47(B), 8(C), 19(D), 16(DR), 3(DQ), and 6(DP). The A, B, and DR proteins are regarded as the most important in clinical transplantation. The HLA genes concentrated within a defined area of chromosome 6 are inherited as a packet or haplotype. Each individual inherits a haplotype of HLA genes from each parent concurrently, and both contribute to the offspring's HLA profile. The parent donor and child recipient share 50% of the haplotypes; a child typically has one representative antigen from class I, II, and III loci of each parent, whereas among siblings, all, some, or no haplotypes may be shared (2 haplotype, 1 haplotype, or 0 haplotype match). By definition, in the absence of recombination, a child is a 1 haplotype match to each parent and transmission (inheritance) of haplotypes occurs in a co-dominant mendelian fashion (Fig. 528–2). In the genetically related donor/recipient pair, the probability of a good HLA match increases and graft loss decreases.

Cellular expression of class I and II antigens, restricted to B and T lymphocytic cells

and macrophages, multiplies with inflammation and by the action of lymphokines (interleukins 2, 4, and 5) secreted by T cells. CD4 (T-helper) and CD8 (T-suppressor) cell surface markers have high affinity for MHC (HLA) class I (histocompatibility) antigens. When attached to cells displaying class I antigen, they transmit signals to synthesize cytokines or to lyse cells. In the acute and chronic rejection reaction, both cellular and humoral mechanisms damage the graft, whereas antibodies, preformed or induced by T-helper cells, mediate accelerated (hyperacute) forms of the rejection reaction (Fig. 528–3). In the cellular variety, the graft is infiltrated by lymphocytes—T-helper and suppressor cells, B lymphocytes, macrophages, plasma cells, and monocytes—resulting in hemorrhage, edema, accumulation of polymorphonuclear leukocytes, activated platelets, and clotting.

Clinically, rejection is manifested by swelling and tenderness of the graft, fever, oliguria, hypertension, and progressive elevation of serum creatinine level. Renal ultrasonography may reveal an enlarged graft with echogenic cortex, and a renal scan demonstrates decreased blood flow. Graft biopsy material shows signs of rejection with relatively intact glomeruli, mild ultrastructural changes, and negative glomerular immunofluorescence. Differentiation between rejection, acute tubular necrosis, cyclosporine toxicity, and de novo occurrence of the original renal disease in the graft requires a kidney biopsy. *Hyperacute* or *accelerated rejections* are seldom observed because pretransplant cross matching detects the presence of pre-existing anti-HLA

Figure 528-2 Inheritance of haplotypes and HLA profile in four theoretical siblings. Sibling 1 is a 1 haplotype match to siblings 2 and 3 and a 0 haplotype match to sibling 4. (From Terasaki PI, Park MS, Danovitch GM: Histocompatibility testing, crossmatching and allocation of cadaveric kidney transplants. In Danovitch GM [editor]: *Handbook of Kidney Transplantation.* Boston, Little, Brown & Company, 1992.)

Figure 528-3 A representation of allograft rejection and the proposed sites of action for immunosuppressive medications. (From Shaefer MS, Collier DS: Immunosuppression for solid organ transplantation. *Dialysis Transplant* 1993;22:542.)

antibodies. In this condition, the kidney becomes dark and soft as it is revascularized. Anti-HLA antibodies bind to endothelium, and renal intravascular coagulation destroys glomeruli and peritubular capillaries. Chronic rejection damages mainly arteries and arterioles, which become thickened with obstructed lumens, while glomeruli undergo ischemic wrinkling of the basement membrane, mononuclear cells infiltrate the interstitium, and arteriolar walls may display immunoglobulin deposits.

Histocompatibility testing is considered of paramount importance in prolonging the survival of LRD and CAD-RT. Having HLA-A, -B, -C, and -D/DR identical with an MHC nonstimulatory sibling donor produces the best graft survival results. The second best is the sibling or parent donor who has 1 haplotype match.

Principles of Immunosuppression and Therapy of Rejection Reaction.

Immune system stimulation by foreign protein (renal graft) results in activation of cell-mediated and humoral-mediated immune inflammation with cell destruction or rejection (see Fig. 528–3). (See also Chapter 126 .) To subdue or control this process, which otherwise results in acute graft loss, the use of immunosuppressive medications is mandatory. The current drugs, doses, mechanism(s) of action, and side effects are listed in Table 528–3 and Figure 528–3 .

Sequential immunosuppression with azathioprine, cyclosporine, and low-dose corticosteroids is the most frequently used protocol. However, new corticosteroid and calcineurin inhibitor–sparing protocols have been designed to avoid morbidity (prednisone-prednisolone) and nephrotoxicity (cyclosporine). Fifty percent of pediatric patients with LRD and 65% of those receiving CAD kidneys develop rejection (with one or more acute episodes in most transplants); 62% of first episodes are successfully treated, whereas only 30% can be reversed when four or more crises have occurred. Chronic rejection is relentless and unresponsive to therapy. In addition, concurrent rejection with complications, particularly infection, places patients at higher risk of graft loss or death. If complications occur as a result of immunosuppression, one should treat the complication and abandon the graft. The use of ATGAM or OKT3 prophylactically in the immediate postoperative period improves the short-term graft outcome in 50% of pediatric CAD recipients. In addition, 6 mo after LRD or CAD transplant, these children have lower mean serum creatinine levels, the interval from transplant to first rejection is lengthened, and the 1-yr graft survival is improved.

As opposed to immunosuppression, the result of medications and/or processes that block normal and fully developed T-cell immunologic response, tolerance or nonreactivity to alloantigens is generally induced during the intrauterine development of the immune system or through a variety of mechanisms (see Table 528–3). Achieving permanent immune unresponsiveness to someone else's antigens represents a more logical approach to retain a functional renal graft instead of prolonged use of dangerous medications.

Growth and Renal Transplantation.

Stunted linear growth and, less often, overt malnutrition are complications of chronic renal failure and of ESRD dialysis (see Chapter 527). Although supportive care improves stamina and a sense of well-being develops, only a successful transplant adequately corrects these abnormalities. Most children awaiting RT show retarded growth of 2.8 SD when 5 yr of age or younger, whereas in those with more than one RT, stunting reaches 3.2 SD. RT-related accelerated growth, lasting 6–12 mo, is observed in younger children; in adolescents, a growth spurt has not been documented. Weight

gain, on the other hand, yields mean values similar to normal adolescents for 2–3 yr. Daily corticosteroid treatment retards growth, even at relatively small doses. Every-other-day prednisone use is unpopular in many transplant centers, allegedly because it may precipitate graft rejection. Nevertheless, the validity and success of the every-other-day corticosteroid regimen has been amply demonstrated in children. Steroids may be used daily for 6 mo in decreasing doses, then switched to every other day and tapered to 0.5–0.2?mg/kg given as a single dose every other day.

Judicious use of recombinant human growth hormone before and after RT improves linear growth significantly, although there are contradictory data indicating that graft function may decrease.

Complications.

Complications that develop after RT are summarized in Box 528–4 . Of these, infection is the most common cause of death during the first year after RT. Cytomegalovirus (CMV) infection is common. CMV antibody titers must be routinely screened in the donor and recipient. CMV infection may be primary, transmitted by the RT itself or by blood transfusions, or reactivated by immunosuppression in a seropositive patient (see Table 528–4). The latter disease becomes apparent 1–3 mo after RT. About 90% may be self-limited and asymptomatic, and 5–10% lead to death; direct tissue damage by CMV may also result in graft loss. In addition, CMV disease usually triggers a rejection reaction. This poses a serious therapeutic dilemma: Although immunosuppression may reactivate the disease, it is indispensable for graft retention. Low-dose immunosuppressive agents with the use of antiviral drugs (ganciclovir and anti-CMV immunoglobulin intravenously) control the infection, and kidney biopsy helps monitor the RR. Immunosuppression must be discontinued in systemic (lung, brain, liver) CMV infection. If rejection is unresponsive, the kidney should be abandoned. Concomitant infection with other viruses (varicella-zoster, Epstein-Barr [EBV], herpes simplex, hepatitis) requires thorough investigation and treatment. *Pneumocystis carinii* infection has all but disappeared, owing to prophylactic use of trimethoprim-sulfamethoxazole, which also prevents bacterial urinary tract infections. The mortality of pediatric RT recipients is 4–4.5%; in 40–45% of these, mortality is caused by infection. The 2-yr patient survivals for LRD and CAD-RT are 95% and 92%, respectively.

Box 528-5. Consequences of EBV Growth and High-Risk Factors for the Development of PTLD in Immunosuppressed Patients

CLINICAL SYNDROMES

Mononucleosis

Meningoencephalitis

Hairy, oral leukoplakia

Smooth muscle cell tumors

T-cell lymphomas

Post-transplant lymphoproliferative disorder (PTLD, uncontrolled proliferation of EBV-infected and transformed B cells, in a polyclonal, oligoclonal, and monoclonal fashion)

Non-Hodgkin lymphoma

HIGH RISK FOR PTLD

High EBV-load

Primary EBV infection

High-dose immunosuppression (cyclosporin A, tacrolimus, antilymphocyte antibodies and steroid pulses alone or combinations)

Cardiac treatment is most commonly affected.

EBV = Epstein-Barr virus.

Immunosuppression remains an unavoidable requisite for transplantation. Unfortunately, use of such medications may result in EBV replication, leading to aggressive and potentially lethal post-transplant lymphoproliferative disorder (PTLD) in 1–2% of renal transplants. In 2001, the NAPRTCS report showed 121 cases of 7,545 transplant patients (1.7% from 1987 to 2000); the HIV-reactivity status of the affected children, however, is not stated. A single center study from France reported 16 PTLD HIV-negative cases out of 1,421 adults (1.1%, mean age 45.5 years; range 27–64 years). PTLD, a rare pre-and fully malignant condition, still is a major cause of serious morbidity and mortality when it develops in young children after the first year post transplantation. This disorder should be actively pursued and diagnosed as early as possible in the febrile transplant patient with lymphadenopathy, gastrointestinal manifestations (abdominal mass, bleeding, pain, obstruction, perforation, ascites), seizures or other central nervous system abnormalities, and asymptomatic chest or mediastinal masses. PTLD is an EBV-CMV infection-driven condition that should be sought after

TABLE 528-2 -- **Rate of Recurrence of Glomerulopathies in Allografts and Graft Loss**

Glomerulopathy	Percent Recurrence	Percent Graft Damage/Loss
FSGS (with NS)	20–40	25
IgA	50	5–10
HSP	30–80	10
MN	20	5–10
MPGN I	25	5–10
MPGN II	90	20
HUS	10–50	10–50
WG	5–20	5–20
AGBM	< 10 (rare in children)	< 1 (uncertain)
SLEGN	5–10	<5
HYPEROX	High	High losses
Cystinosis	Graft handles cystine load	Loss to rejection
IGN (de novo MPGN)	Uncertain	Uncertain

FSGS = focal segmental glomerular sclerosis; IgA = immunoglobulin A nephritis; HSP = Henoch-Schönlein purpura; MN = membranous nephropathy; MPGN I and II = membranoproliferative glomerulonephritis type I and type II; HUS = hemolytic-uremic syndrome; WG = Wegener granulomatosis; AGBM = anti–glomerular basement membrane nephritis; SLEGN = systemic lupus erythematosus glomerulonephritis; HYPEROX = hyperoxalosis/oxaluria; IGN = ideopathic glomerulonephritis.

TABLE 528-3 -- Immunosuppressive Agents

Substance	Mechanism	Dose	Side Effects
Nonselective Antiproliferatives			
Azathioprine (Imuran)	Inhibits enzyme critical to formation of purine nucleosides, 6 thioguanine incorporated into DNA as fraudulent bases.	Alone 2–3?mg/kg/24 hr, combined 1–2?mg/kg/ 24 hr nonrenal excretion	Bone marrow suppression, liver cell damage, chromosomal breakage, and tumor growth
Cyclophosphamide (Cytoxan)	Radiomimetic—alkylating substance that inhibits rapidly replicating cells, by cross linking with cell DNA.	1–2?mg/kg/24 hr orally. IV pulses of 750?mg/m^2 /BSA with normal GFR; decrease to 500?mg/m^2 BSA if GFR is impaired	Bone marrow suppression, infections, gastrointestinal problems, alopecia, hemorrhagic cystitis, tumors
Mycophenolate mofetil (Cell Cept)	Interferes with purine synthesis. Stops progression of activated T and B cells in S phase of cell cycle. May also alter *N*-glycosulation of cell membrane glycoproteins.	1–3?g day PO; usually combined with prednisone and cyclosporin A	Gastrointestinal: esophagitis, gastritis, diarrhea, and bleeding; increased susceptibility to CMV, infection, tumors
Selective Inhibitors			
Calcineurin inhibitors Cyclosporin A (NEORAL)	Blocks calcineurin and inhibits cytokine synthesis; T-cell selective inhibitor inhibits interleukin 2 (IL-2).	4?mg/kg/24 hr (follow trough blood levels for dose adjustments)	Hirsutism, gingival hyperplasia, arterial hypertension, renal arteriolitis, nonmyelodepressant tremors (CNS toxicity)
Tacrolimus (Prograf)	Same mechanisms.	0.15–0.20?mg/kg divided q12 hr	As above—nephrotoxic, posttransplant IDDM (higher in African American patients)
Sirolimus (Rapamycin) Rapamycin Analog (SDZ-RAD)	Blocks cytokine-driven cell proliferation and maturation.	7.5?mg/m^2 BSA × 5 days and 5?mg/m^2 with other drugs	Thrombocytopenia, hyperlipidemia
Polyclonal antilymphocyte antibodies (equine ATGAM and rabbit thymoglobulin)	Antibodies bind to cell surface receptors opsonizing cells for complement-induced lysis/phagocytosis.	ATGAM: Infusion with in-line filter into central line only, over 4 hr, 14–21 days; thymoglobulin: peripheral IV 6 hr, 1.5?mg/kg/24 hr, 14–21 days	Profound immunosuppression <150–<50 peripheral blood T-lymphocyte cell count/mm^3 ; chills, fever, arthralgias thrombocytopenia and leukocytopenia; CMV infection, tumors
Monoclonal antibodies (OKT3 Orthoclone)	Produced by hybridomas/murine spleen cells of mice immunized against human lymphocytes. Bind CD_3 receptor on T cells: modulation and immunologic inactivation of CD_3 .	For induction therapy and reversal of steroid resistant rejection reaction, 1–5?mg/dose/24 hr	Cytokine release syndrome: tumor necrosis factor, IL-2, interferon- ? fever, chills, tremors, chest pain, wheezing, nausea, and vomiting
Interleukin-2 receptor monoclonal antibodies Basiliximab Daclizumab	Blocks the IL-2 receptor and prevents cellular activation; does not produce cytokine release syndrome; does not induce neutralizing antibodies.	Basiliximab: 20?mg IV day of surgery and day 4 Daclizumab: 1?mg/kg/IV within 24 hr of transplant followed by same dose every 2 wk × 5	Immunosuppression
B-and T-Cell Stimulators			
Janus Kinase (JAK3) inhibitor (AG490). And C-RAF isoform specific enzyme inhibitor	Inhibits IL-2 cytokine receptors.	No clinical data yet available	
Ischemia/Reperfusion-Induced Tissue Damage Inhibitors			
Selectin-blocking agents	Interrupt and modulate effects of adhesion molecules (selectin; integrin, ICAM-1, VCAM, and VLA-4).		
KPL1 antibody (TBC-1269 and CY 1503)	Monoclonal antibody to selectin; inhibits leukocyte recruitment.	No clinical data yet available	PTT prolongation, mild complement activation

FTY 720 (sphyngosine-like compound)	Alters leukocyte recirculation pattern diverting them away from the graft to lymphoid tissues; inhibits lymphocyte receptors, and blocks interaction with integrins.	0.25–3.5?mg (single dose)	Lymphopenia, bradycardia
Transplantation Tolerance			
Induction of anergy by inactivation or deletion of antigen reactive cells			
Alloantigen unresponsiveness			
T-cell co-stimulation (CTLA-4Ig: competitive inhibitor of T-cell Surface markers)	Insufficient clinical data		
Allochimeric molecules (derived from class I–II major histocompatibility (HLA) complex	Insufficient clinical data		
Gene therapy	Insufficient clinical data

Modified from Hong JC, Kahan BD: Immunosuppressive in organ transplantation: Past, present and future. Semin Nephrol *2000; 20: 108–125.*

BSA = body surface area; CMV = cytomegalovirus; CNS = central nervous system; GFR = glomerular filtration rate; IL- 2 = interleukin-2; PTT = partial thromboplastin time.

TABLE 528-4 -- **Types of Cytomegalovirus in the Pediatric Renal Transplant Recipient**

Type of Infection	Type of Patient	Symptomatic	Prevention
Primary	Seronegative with seropositive kidney, transfusion of leukocytes, blood products transfusion	60%	Avoidance of CMV infection or use active immunization (live attenuated vaccine: Towne strain; not very effective)
Reactivation	Seropositive before transplantation	<20%	High titer human hyperimmune anti-CMV globulin (CytoGam)
Superinfection	Seropositive patient transplanted with CMV + kidney	40%	Human IgG concentrates (CMV nonspecific Gammagard or Polygam)

CMV-cytomegalovirus.

From Snydman DR: Prevention of cytomegalovirus-associated diseases with immunoglobulin. Transplant Proc *1991;23:131.*

clinically by tissue sampling and all possible laboratory means: polymerase chain reaction (PCR)-determined EBV-CMV blood viral load, RNA or DNA positivity and clonality by Southern blot analysis, and latent membrane protein 1 (LMP 1) expression in paraffin embedded tissue samples and frozen tissue studies. The clinical consequences of EBV growth and the high risks for the development of PTLD in the immunosuppressed patient are listed earlier in Box 528–5 .

PTLD that occurs less than 1 yr post transplant generally exhibits a much more benign prognosis and may respond and regress by simple reduction or by discontinuation of immunosuppressive medications. Of the 16 patients with severe disease (PTLD of late onset) in the previously mentioned French study, 11 individuals received full chemotherapy (CHOP protocol: cyclophosphamide, doxorubicin, vincristine, and prednisone) with 6 achieving complete and persistent remission. The use of the CHOP protocol by these clinicians revealed no nephrotoxicity, and most patients did not mount a renal rejection reaction when, for a variable but limited period, low or no maintenance immunosuppressive medications were given after antitumor therapy was completed.

Renal Transplant in the HIV-Infected Patient.

With the development of effective antiretroviral therapy, prognosis of the HIV-infected patient has improved enough to consider renal transplant in these cases on an individual basis. The conditions to perform a renal transplant or retransplant in HIV-infected patients require that the candidate is free of opportunistic infections for 2 yr and is on a stable and well-tolerated anti-HIV/*Pneumocystis* regimen. Good compliance and undetectable viral load (by PCR), acceptable CD4 lymphocyte count, and no complicating illnesses are mandatory.

Recurrence of Glomerular Disease in the Graft.

Potentially all glomerulopathies can recur in the transplant (see Table 528–2)

TABLE 528-5 -- **FSGS: Clinical Characteristics and Effects on the Allograft**

Effects on Native Kidney	Effects on Allograft	Forms of Therapy
Severe progressive FSGS and hypercellularity. Clinically, nephrotic syndrome, chronic renal failure with progression to ESRD in 60% of cases.	Histologic recurrence of FSGS in graft 20–40% Recurrent nephrotic syndrome, renal failure, ESRD in 25%.	Avoid living related donor and high cyclosporin A dose. To treat, use plasmapheresis-exchange and immunoadsorption, cyclophosphamide, and OKT3. Pretransplant bilateral nephrectomy should not be done. All forms of treatment seem purely palliative.
Dialysis and transplantation needed.	*Favor recurrence*: <6 yr, rapidly progressive renal failure, glomerular hypercellularity, previous recurrence, closely matched living related donor, familial distribution of FSGS, presence of assayable high levels of permeability factor in recipient's blood.	

ESRD= end-stage renal disease; FSGS = focal segmental glomerular sclerosis.

with 5–10% of all allografts lost through this mechanism. Of these, focal segmental glomerular sclerosis is perhaps the most frequent, has poorly known mechanisms, and is difficult to treat (Table 528–5).

The hemolytic-uremic syndrome (HUS) does not recur but may happen de novo in the allograft. The familial non–infection-related variety of HUS, presumably genetically transmitted, does develop de novo (1–3%) or may be associated with calcineurin-inhibitor mediation (cyclosporine and others) but is more frequent in bone marrow grafts than in renal transplants. Important predictors for the development of non–infection-related HUS occurrences in the renal graft include familial disease (autosomal dominant or recessive), transplant before 6 mo to 1 yr after primary disease remitted completely, and use of cyclosporine (low dose is recommended if recurrence developed in previous transplant). Using LRDs in cases known to have familial prostacyclin synthesis abnormalities, consumption of oral contraceptive medications, and employing ATGAM and OKT3 have been associated with post-transplant de novo HUS.

Part 23 - Urologic Disorders in Infants and Children

Jack S. Elder

Chapter 529 - Congenital Anomalies and Dysgenesis of the Kidneys

The kidney is derived from the ureteral bud and the metanephric blastema. During the 5th wk of gestation, the ureteral bud arises from the mesonephric (wolffian) duct and penetrates the metanephric blastema, which is an area of undifferentiated mesenchyme on the nephrogenic ridge. The ureteral bud undergoes a series of approximately 15 generations of divisions and by 20 wk of gestation forms the entire collecting system: the ureter, renal pelvis, calyces, papillary ducts, and collecting tubules. Under the inductive influence of the ureteral bud, nephron differentiation begins during the 7th wk of gestation. By 20 wk of gestation, when the collecting system is developed, approximately 30% of the nephrons are present. Nephrogenesis continues at a nearly exponential rate and is complete by 36 wk of gestation.

The fetal kidneys play a minor role in the maintenance of fetal salt and water homeostasis. The rate of urine production increases throughout gestation and, at term, volumes have been reported to be 51?mL/hr. The glomerular filtration rate is 25?mL/min/1.73?m^2 at term and thereafter triples by 3 mo of age. The increase in glomerular filtration rate is caused by a reduction in intrarenal vascular resistance and redistribution of intrarenal blood flow to the cortex, where more nephrons are located.

Dysgenesis of the kidney includes aplasia, dysplasia, hypoplasia, and cystic disease.

Renal Agenesis.

Bilateral renal agenesis is incompatible with extrauterine life. Death occurs shortly after birth from pulmonary hypoplasia. This condition is termed *Potter syndrome*. The newborn has a characteristic facial appearance, termed *Potter facies* (Fig. 529–1).

The eyes are widely separated and have epicanthic folds, the ears are low set, the nose is broad and compressed flat, the chin is receding, and there are limb anomalies. Bilateral renal agenesis should be suspected when maternal ultrasonography demonstrates oligohydramnios, nonvisualization of the bladder, and absent kidneys. The incidence is 1 in 3,000 births and represents 20% of newborns with the Potter phenotype. Other common causes of neonatal renal failure associated with the Potter phenotype include cystic renal dysplasia and obstructive uropathy. Less common causes are autosomal recessive polycystic kidney disease (infantile), renal hypoplasia, and medullary dysplasia.

Renal agenesis means that the kidney did not form because of an abnormal ureteral bud and is distinguished from aplasia, an extreme form of dysplasia in which a nubbin of nonfunctioning tissue is seen capping a normal or abnormal ureter. Clinically, this distinction may be difficult. *Hereditary renal adysplasia* is used to describe families in which renal agenesis, renal dysplasia, multicystic kidney (dysplasia), or a combination, occurs in a single family. This disorder has an autosomal dominant inheritance pattern with a penetrance of 50–90% and variable expression. Associated anorectal, cardiovascular, and skeletal abnormalities are seen in newborns with both hereditary renal adysplasia and bilateral renal agenesis.

Unilateral renal agenesis is often discovered during the course of an evaluation for other congenital anomalies or for urinary tract symptoms. Its incidence is increased in newborns with a single umbilical artery. With true agenesis, the ureter and the ipsilateral bladder hemitrigone are absent. The contralateral kidney undergoes compensatory hypertrophy, to some degree prenatally but primarily after birth. Approximately 15% have contralateral vesicoureteral reflux, and most males have an ipsilateral absent vas deferens because the wolffian duct is absent. Because the wolffian and müllerian ducts are contiguous, müllerian abnormalities in girls are also common. The *Mayer-Rokitansky-Kuster-Hauser syndrome* refers to a group of associated findings that include unilateral renal agenesis or ectopia, ipsilateral müllerian defects, and vaginal agenesis. Some individuals are diagnosed as having unilateral renal agenesis based on a finding of an absent kidney on ultrasonography or excretory urography. Some of these patients actually were born with a hypoplastic kidney or a multicystic dysplastic kidney that underwent complete cyst regression. The specific diagnosis is not critical. However, if the finding of an absent kidney is based on an ultrasonogram, a functional imaging study such as an excretory urogram or renal scan should be performed because

Figure 529-1 Stillborn with renal agenesis exhibiting the characteristic Potter facies. (Courtesy of Barbara Burke, MD, Department of Laboratory Medicine and Pathology. University of Minnesota Hospital, Minnesota.)

some of these patients may have an ectopic kidney. If there is a normal contralateral kidney, renal function should remain normal over time.

Whether individuals with a solitary kidney should avoid contact sports such as football and karate is unresolved. The arguments favoring participation are that there are other solitary organs such as the spleen, liver, and brain that do not preclude contact sport participation, and there have been few reports of individuals losing a kidney from sports injuries. The arguments against such participation are that the contralateral normal kidney is hypertrophic and not as well protected by the ribs, and a serious renal injury could have devastating life-long consequences. The American Academy of Pediatrics recommends an "individual assessment for contact, collision, and limited-contact sports."

Renal Dysplasia and Hypoplasia.

The term *dysplasia* is technically a histologic diagnosis and refers to focal, diffuse, or segmentally arranged primitive structures, specifically primitive ducts, resulting from abnormal metanephric differentiation. Nonrenal elements, such as cartilage, may be present. The condition may affect all or only part of the kidney. If cysts are present, the condition is termed *cystic dysplasia*. If the entire kidney is dysplastic with a preponderance of cysts, the kidney is referred to as a *multicystic dysplastic kidney* (Fig. 529–2). The pathogenesis of dysplasia is multifactorial. The "bud" theory proposes that if the ureteral bud arises in an abnormal location, such as an ectopic ureter, there is inappropriate penetration and induction of the metanephric blastema that causes abnormal kidney differentiation-dysplasia. Renal dysplasia may also occur with severe obstructive uropathy early in gestation, as with the most severe cases of posterior urethral valves or in a multicystic dysplastic kidney, in which a portion of the ureter is absent or atretic.

A multicystic kidney is a congenital condition in which the kidney is replaced by cysts, does not function, and may result from ureteral atresia. Renal size is highly variable. The incidence is approximately 1 in 2,000. Clinicians may incorrectly assume that *multicystic kidney* and *polycystic kidney* are synonymous terms. Polycystic kidney disease is an inherited disorder that may be autosomal recessive or autosomal dominant and affects both kidneys (see Chapter 513). A multicystic kidney is usually

Figure 529-2 Surgical specimen of a multicystic dysplastic kidney associated with ureteral atresia.

unilateral and is not inherited. Bilateral multicystic kidneys are incompatible with life.

Multicystic dysplastic kidney is the most common cause of an abdominal mass in the newborn. In many cases it is discovered incidentally during antenatal sonography. In some individuals, the cysts are identified prenatally or postnatally, but no renal tissue is identified because of cyst regression in utero. Contralateral vesicoureteral reflux is identified in 15%, and contralateral hydronephrosis is present in 5–10% of patients. Sonography shows the characteristic appearance of a kidney replaced by multiple cysts of varying sizes that do not communicate, and no identifiable parenchyma is present; the diagnosis should be confirmed with a renal scan, which should demonstrate nonfunction. A voiding cystourethrogram is also advisable because of a 15% incidence of contralateral reflux. Management is controversial. There have been a few reports of renin-mediated hypertension and Wilms tumor arising in these kidneys. Neoplasms arise from the stromal, not the cystic, component. Consequently, even if the cysts regress completely, the likelihood that the kidney could develop a neoplasm is not altered. Because of the occult nature of these potential problems, annual follow-up with sonography and blood pressure measurements is recommended. If there is an abdominal mass, the cysts enlarge,

the stromal core increases in size, or hypertension develops, nephrectomy is recommended. Alternatively, in lieu of follow-up screening, nephrectomy may be performed through a 2.5- to 3-cm flank incision when the child is 6–12 mo old. The Section on Urology of the American Academy of Pediatrics has an ongoing registry to determine the long-term risk of the nonoperative management of multicystic kidneys.

Renal hypoplasia refers to a small nondysplastic kidney that has less than the normal number of calyces and nephrons. The term refers to a group of conditions with an abnormally small kidney and should be distinguished from aplasia, in which the kidney is rudimentary. If the condition is unilateral, the diagnosis usually is made incidentally during evaluation for another urinary tract problem or hypertension. Bilateral hypoplasia usually presents with the manifestations of chronic renal failure and is a leading cause of end-stage renal disease during the first decade of life. A history of polyuria and polydipsia is common. Urinalysis results may be normal. A rare form of bilateral hypoplasia is called *oligomeganephronia,* in which the number of nephrons is markedly reduced but those present are markedly hypertrophied.

The *Ask-Upmark kidney,* also termed *segmental hypoplasia,* refers to small kidneys, usually weighing not more than 35?g, with one or more deep grooves on the lateral convexity, underneath which the parenchyma consists of tubules resembling those in the thyroid gland. It is unclear whether the lesion is congenital or acquired. Most patients are 10 yr or older at diagnosis and have severe hypertension. Nephrectomy usually controls the hypertension.

Anomalies in Shape and Position.

During renal development the kidneys normally ascend from the pelvis into their normal position behind the ribs. The normal process of ascent and rotation of the kidney may be incomplete, resulting in renal ectopia or nonrotation. The ectopic kidney may be in a pelvic, iliac, thoracic, or contralateral position. If it is contralateral, in 90% of individuals there is fusion of the two kidneys. The incidence of renal ectopia is approximately 1 in 900.

Renal fusion anomalies are common. The lower poles of the kidneys may fuse in the midline, resulting in a *horseshoe kidney* (Fig. 529–3). Horseshoe kidneys occur in 1 in 500 births but are seen in 7% of patients with Turner syndrome. Horseshoe kidney is one of the many renal anomalies that occur in 30% of these patients. Wilms tumors are four times more frequent in children with horseshoe kidneys than in the general population. In addition, stone disease and hydronephrosis secondary to

Figure 529-3 Isotopic renogram showing the characteristic configuration of a horseshoe kidney with an isthmus of functioning parenchyma.

ureteropelvic junction obstruction are potential late complications. There also appears to be a slightly increased incidence of multicystic dysplastic kidney affecting one of the two sides of a horseshoe kidney. With *crossed fused ectopia*, one kidney crosses over to the other side and the parenchyma of the two kidneys fuse. Renal function is generally normal. The most common finding is that the left kidney may cross over and fuse with the lower pole of the right kidney. The insertion of the ureter does not change. In addition, the adrenal glands remain in their normal positions. The clinical significance of this anomaly is that if renal surgery is necessary, the blood supply is variable and may make partial nephrectomy more difficult.

Associated Physical Findings.

Upper urinary tract anomalies are more common in children with certain physical findings. For example the incidence of renal anomalies is increased if there is a single umbilical artery and an abnormality of an organ system (e.g., congenital heart disease). In addition, external ear anomalies (particularly if the child has multiple congenital anomalies), imperforate anus, and scoliosis are associated with renal anomalies. Babies with these physical findings should undergo a renal sonogram.

Chapter 530 - Urinary Tract Infections (See also Chapter 511 .)

Prevalence and Etiology.

Urinary tract infections (UTIs) occur in 3–5% of girls and 1% of boys. In girls, the first UTI usually occurs by the age of 5 yr, with peaks during infancy and toilet training. After the first UTI, 60–80% of girls will develop a second UTI within 18 mo. In boys, most UTIs occur during the 1st yr of life; UTIs are much more common in uncircumcised boys. The prevalence of UTIs varies with age. During the 1st yr of life, the male:female ratio is 2.8–5.4:1. Beyond 1–2 yr, there is a striking female preponderance, with a male:female ratio of 1:10.

UTIs are caused mainly by colonic bacteria. In females, 75–90% of all infections are caused by *Escherichia coli*, followed by *Klebsiella* and *Proteus*. Some series report that in males older than 1 yr of age, *Proteus* is as common as *E. coli*; others report a preponderance of gram-positive organisms in males. *Staphylococcus saprophyticus* is a pathogen in both sexes. Viral infections, particularly adenovirus, may also occur, especially as a cause of cystitis.

UTIs have been considered an important risk factor for the development of renal insufficiency or end-stage renal disease. Some have questioned the importance of UTI as a risk factor because only 2% of children with current renal insufficiency report a history of UTI. This paradox is probably secondary to better recognition of the risks of UTI and prompt diagnosis and therapy.

Clinical Manifestations and Classification.

There are three basic forms of UTI: pyelonephritis, cystitis, and asymptomatic bacteriuria.

Pyelonephritis is characterized by any or all of the following: abdominal or flank pain, fever, malaise, nausea, vomiting, and occasionally diarrhea. Some newborns and infants may show nonspecific symptoms such as jaundice, poor feeding, irritability, and weight loss. These symptoms are an indication that there is bacterial involvement of the upper urinary tract. Involvement of the renal parenchyma is termed *acute pyelonephritis*, whereas if there is no parenchymal involvement, the condition may be termed *pyelitis.* Acute pyelonephritis may result in renal injury, which is termed **pyelonephritic scarring**.

Cystitis indicates that there is bladder involvement and symptoms include dysuria,

urgency, frequency, suprapubic pain, incontinence, and malodorous urine. Cystitis does not cause fever and does not result in renal injury.

Asymptomatic bacteriuria refers to individuals who have a positive urine culture without any manifestations of infection and occurs almost exclusively in girls. This condition is benign and does not cause renal injury, except in pregnant women, in whom asymptomatic bacteriuria, if left untreated, can result in a symptomatic UTI. Some girls are mistakenly identified as having asymptomatic bacteriuria, whereas they actually are symptomatic, experiencing day or night incontinence or perineal discomfort.

Pathogenesis and Pathology.

Nearly all UTIs are ascending infections. The bacteria arise from the fecal flora, colonize the perineum, and enter the bladder via the urethra. In uncircumcised boys, the bacterial pathogens arise from the flora beneath the

prepuce. In some cases, the bacteria ascend to the kidney to cause pyelonephritis. In rare cases, renal infection may occur by hematogenous spread.

If bacteria ascend from the bladder to the kidney, acute pyelonephritis may occur. Normally the simple and compound papillae in the kidney have an antireflux mechanism that prevents urine from flowing in a retrograde manner into the collecting tubules. Some compound papillae, typically located in the upper and lower poles of the kidney, allow intrarenal reflux. Infected urine then stimulates an immunologic and inflammatory response (Fig. 530–1). The result may cause renal injury and scarring (Fig. 530–2).

Children of any age with a febrile UTI may have acute pyelonephritis with renal scarring. The exception to this observation is that if a child with UTIs has a normal 2,3-dimercaptosuccinic acid (DMSA) scan by 4 yr of age, the risk of pyelonephritogenic scarring from future UTIs is probably low.

Host risk factors for UTI are listed in Box 530–1 . Vesicoureteral reflux is discussed in Chapter 531 . In girls, UTIs often occur at the onset of toilet training because of voiding dysfunction that occurs at that age. The child is trying to retain urine to stay dry, yet the bladder may have uninhibited contractions forcing urine out. The result may be high-pressure, turbulent urine flow or incomplete bladder emptying, both of which increase the likelihood of bacteriuria. Voiding dysfunction may occur in the toilet-trained child who voids infrequently. Obstructive uropathy resulting in hydronephrosis increases the risk of UTI because of urinary stasis. Urethral instrumentation during a voiding cystourethrogram or nonsterile catheterization may infect the bladder with a pathogen. Constipation can increase the risk of UTI because it may cause voiding dysfunction.

The pathogenesis of UTI is based in part on the presence of bacterial pili or fimbriae on the bacterial surface. There are two types of fimbriae, type I and type II. Type I

fimbriae are found on most strains of *E. coli*. Because attachment to target cells can be blocked by D-mannose, these fimbriae are referred to as “mannose-sensitive.” They have no role in pyelonephritis. The attachment of type II fimbriae is not inhibited by mannose, and

Figure 530-1 Pathogenesis of pyelonephritic scarring following acute pyelonephritis. (Adapted from Roberts JA: Pathogenesis of pyelonephritis. *J Urol* 1983;129:1102.)

Figure 530-2 Scarred kidney from recurrent pyelonephritis.

these are known as “mannose-resistant.” These fimbriae are expressed by only certain strains of *E. coli*. The receptor for type II fimbriae is a glycosphingolipid that is present on both the uroepithelial cell membrane and red blood cells. The Gal 1–4 Gal oligosaccharide fraction is the specific receptor. Because these fimbriae can agglutinate by P blood group erythrocytes, they are known as P fimbriae. Bacteria with P fimbriae are more likely to cause pyelonephritis. Between 76–94% of pyelonephritogenic strains of *E. coli* have P fimbriae, compared with 19–23% of cystitis strains.

Other host factors for UTI include anatomic abnormalities precluding normal micturition, such as a labial adhesion. This lesion acts as a barrier and causes vaginal voiding. A neuropathic bladder may cause UTIs if there is incomplete bladder emptying or detrusor-sphincter dyssynergia, or both. Sexual activity is associated with UTIs in girls, in part because of incomplete bladder emptying. Finally, during pregnancy 4–7% have asymptomatic bacteriuria, which can result in a symptomatic UTI. The incidence of UTI in infants who are breast fed is lower than in those fed with formula.

Xanthogranulomatous pyelonephritis is a rare type of renal infection characterized by granulomatous inflammation with giant cells and foamy histiocytes. It may present clinically as a renal mass or an acute or chronic infection. Renal calculi, obstruction, and infection with *Proteus* or *E. coli* contribute to the development of this lesion, which usually requires total or partial nephrectomy.

Diagnosis.

A UTI may be suspected based on the symptoms or findings on urinalysis, or both, but a urine culture is necessary

Box 530-1. Risk Factors for Urinary Tract Infection

*Risk increased for clinical pyelonephritis, not cystitis.

for confirmation and appropriate therapy. Thus, the diagnosis of UTI depends on having the proper sample of urine. There are several ways to obtain a urine sample; some are more accurate than others.

In toilet-trained children, a *midstream urine sample* is usually satisfactory. Most studies have failed to show any benefit to formally cleansing the introitus before obtaining the specimen. If the culture shows greater than 100,000 colonies of a single pathogen, or if there are 10,000 colonies and the child is symptomatic, it is considered a UTI. In uncircumcised males, the prepuce must be retracted; if the prepuce is not retractable, this method of urine collection is unreliable.

In infants, the application of an adhesive, sealed, *sterile collection bag* after disinfection of the skin of the genitals can be useful, particularly if the culture is negative. However, a positive culture may reflect a contaminant, particularly in girls and uncircumcised boys. In such cases, if the urinalysis result is positive, the patient is symptomatic, and there is a single organism cultured with a colony count greater than 100,000, there is a presumed UTI. However, if any of these criteria are not met, confirmation of infection with a catheterized sample is recommended (see next paragraph).

When greater assurance as to the possibility of infection is needed, a *catheterized specimen* must be obtained. Proper skin preparation and good technique of catheterization are important. The use of a No. 5 French polyethylene feeding tube in infants or a No. 8 French tube with proper lubrication in older children minimizes the chance of urethral trauma and contamination. Only a few milliliters need to be aspirated with a syringe to obtain the urine sample. Catheterization shortly after spontaneous voiding produces a measure of the residual urine in the bladder and helps assess problems related to bladder emptying.

Prompt plating of the urine sample is important because if the urine sits at room temperature for more than 60 min, overgrowth of a minor contaminant may suggest a UTI, when in fact the urine may not be infected. Placing the sample in a refrigerator is a reliable method of storing the urine until it can be cultured.

A urinalysis should be obtained from the same specimen as that cultured. Pyuria (leukocytes in the urine) suggests infection, but infection can occur in the absence of pyuria; consequently, this finding is more confirmatory than diagnostic. Conversely, pyuria can be present without UTI. Nitrites and leukocyte esterase are usually positive in infected urine. Microscopic hematuria is common in acute cystitis. White blood cell casts in the urinary sediment suggest renal involvement, but these are rarely seen. If the child is asymptomatic and the urinalysis result is normal, it is unlikely that the urine is infected. However, if the child is symptomatic, a UTI is possible, even if the urinalysis result is negative.

With acute renal infection, leukocytosis, neutrophilia, and elevated erythrocyte sedimentation rate and C-reactive protein are common. The latter two are nonspecific markers of bacterial infection, and their elevation does not mean that the child has acute pyelonephritis. With a renal abscess, the white blood cell count is markedly elevated to greater than 20,000 to 25,000/mm^3 . Because sepsis is common in pyelonephritis, particularly in infants and in any child with obstructive uropathy, blood cultures should be considered.

Acute hemorrhagic cystitis is frequently caused by *E. coli*; it has been attributed also to adenovirus types 11 and 21. Adenovirus cystitis is more frequent in males; it is self-limiting, with hematuria lasting approximately 4 days.

Eosinophilic cystitis is a rare form of cystitis of obscure origin that occasionally is found in children. The usual symptoms are those of cystitis with hematuria, ureteral dilatation with occasional hydronephrosis, and filling defects in the bladder caused by

masses that consist histologically of inflammatory infiltrates with eosinophils. Children with eosinophilic cystitis may have had exposure to an allergen. Frequently, bladder biopsy is necessary to exclude a neoplastic process. Treatment usually includes antihistamines and nonsteroidal anti-inflammatory agents, but in some cases intravesical dimethyl sulfoxide instillation is necessary.

Interstitial cystitis is characterized by irritative voiding symptoms such as urgency, frequency, and dysuria, and bladder and pelvic pain relieved by voiding with a negative urine culture. The disorder is most likely to affect adolescent girls and is idiopathic. Diagnosis is made by cystoscopic observation of mucosal ulcers with bladder distention. Treatments have included bladder hydrodistention and laser ablation of ulcerated areas, but no treatment yields sustained relief.

Treatment.

Acute cystitis should be treated promptly to prevent its possible progression to pyelonephritis. If the symptoms are severe, a specimen of bladder urine is obtained for culture and treatment is started immediately. If the symptoms are mild or the diagnosis is doubtful, treatment can be delayed until the results of culture are known, and the culture can be repeated if the results are uncertain. For example, if a midstream culture grew between 10^4 and 10^5 colonies of a gram-negative organism, a second culture may be obtained by catheterization before treatment is initiated. If treatment is initiated before the results of a culture and sensitivities are available, a 3- to 5-day course of therapy with trimethoprim-sulfamethoxazole (see later) is effective against most strains of *E. coli*. Nitrofurantoin (5–7?mg/kg/24?hr in three to four divided doses) is also effective and has the advantage of being active against *Klebsiella-Enterobacter* organisms. Amoxicillin (50?mg/kg/24?hr) is also effective as initial treatment but has no clear advantages over the sulfonamides or nitrofurantoin.

In acute febrile infections suggestive of pyelonephritis, a 14-day course of broad-spectrum antibiotics capable of reaching significant tissue levels is preferable. Children who are dehydrated, are unable to drink fluids, or in whom sepsis is a possibility should be admitted to the hospital for intravenous rehydration and intravenous antibiotic therapy. Parenteral treatment with ceftriaxone (50–75?mg/kg/24?hr, not to exceed 2?g) or ampicillin (100?mg/kg/24?hr) with an aminoglycoside such as gentamicin (3 to 5?mg/kg/24?hr in one to three divided doses) is preferable. The potential ototoxicity and nephrotoxicity of aminoglycosides should be considered, and serum creatinine and trough gentamicin levels must be obtained before initiating treatment as well as daily thereafter as long as treatment continues. Treatment with aminoglycosides is particularly effective against *Pseudomonas,* and alkalinization of urine with sodium bicarbonate increases their effectiveness in the urinary tract. Oral third-generation cephalosporins such as cefixime are as effective as parenteral ceftriaxone against a variety of gram-negative organisms other than *Pseudomonas,* and these medications are considered by some authorities to be the treatment of choice for oral therapy.

Nitrofurantoin should not be used in children with a febrile UTI because it does not achieve significant renal tissue levels. The oral fluoroquinolone ciprofloxacin is an alternative agent for resistant microorganisms, particularly *Pseudomonas,* in patients older than 17 yr. It also has been used in younger children with cystic fibrosis and pulmonary infection secondary to *Pseudomonas* and is used on occasion for short course therapy in children with *Pseudomonas* UTI. However, the clinical use of fluoroquinolones in children should be restricted because of potential cartilage damage that occurred in research with immature animals. The safety and efficacy of oral ciprofloxacin in children is under study. In some children with a febrile UTI, intramuscular injection of a loading dose of ceftriaxone followed by oral therapy with a third-generation cephalosporin is effective.

Children with a renal or perirenal abscess or with infection in obstructed urinary tracts require surgical or percutaneous drainage in addition to antibiotic therapy and other supportive measures.

A urine culture should be performed 1 wk after the termination of treatment of any UTI to ensure that the urine is sterile. Given the tendency of urinary tract infections to recur even in the absence of predisposing anatomic factors, a follow-up urine culture should be performed periodically for 1–2 yr, even when the child is asymptomatic.

If recurrences are frequent, identifying predisposing factors to UTI is beneficial. For example, many school-aged girls have voiding dysfunction, and treatment of this condition often reduces the likelihood of recurrent UTI. Some children with urinary tract infections void infrequently, and many also have severe constipation. Counseling of parents and patients to try to establish more normal patterns of voiding and defecation may be helpful in controlling recurrences. In addition, prophylaxis against reinfection, using either the sulfamethoxazole-trimethoprim combination or nitrofurantoin at one third of the normal therapeutic dose once a day, is often effective. Prophylaxis with amoxicillin or cephalexin also may be effective, but the risk of breakthrough UTI is higher because bacterial resistance may be induced. Other indications for long-term prophylaxis (neurogenic bladder, urinary tract stasis and obstruction, reflux, and calculi) are discussed in other chapters. Cranberry juice has not proved beneficial in preventing UTI.

The main consequences of chronic renal damage caused by pyelonephritis are arterial hypertension and renal insufficiency; when they are found they should be treated appropriately (see Chapters 437 and 527).

Imaging Studies.

The goal of imaging studies in children with a UTI is to identify anatomic abnormalities that predispose to infection. A renal ultrasonogram should be obtained to rule out hydronephrosis and renal or perirenal abscesses; ultrasonography also may show acute pyelonephritis (in 30–60% of cases) by demonstrating an enlarged kidney. Power Doppler ultrasonography has been slightly more sensitive but is unreliable in identifying all cases. Ultrasonography demonstrates 30% of renal scars. Normally, the difference in renal lengths between the two kidneys is less than 1?cm, and a larger disparity may be an indication of impaired renal growth. One should remember that in a child with acute pyelonephritis, a small kidney may be enlarged because of the infection, giving the erroneous impression that the kidneys are equal in size. Renal ultrasonography is also sensitive for detecting pyonephrosis, a condition that may require prompt drainage of the collecting system by percutaneous

nephrostomy.

A voiding cystourethrogram (VCUG) is also indicated in all children younger than 5 yr with a UTI, any child with a febrile UTI, school-aged girls who have had two or more UTIs, and any male with a UTI. The most common finding is vesicoureteral reflux, which is identified in approximately 40% of patients (Fig. 530–3). Timing of the VCUG is controversial. In some centers the study is delayed for 2–6 wk to allow inflammation in the

Figure 530-3 Intrarenal reflux. Voiding cystourethrogram in a young infant male with a past history of a urinary tract infection. Note the right vesicoureteral reflux with ureteral dilatation, with opacification of the renal parenchyma representing intrarenal reflux.

bladder to resolve. However, the incidence of reflux is identical, irrespective of whether the VCUG is obtained during treatment of the UTI or after 6 wk. Consequently, obtaining the VCUG before the child is discharged from the hospital is recommended. If available, a radionuclide VCUG instead of a contrast VCUG can be used in girls; this technique causes less radiation exposure to the gonads than does the contrast study. However, the radioisotopic VCUG does not provide anatomic definition of the bladder, allow precise grading of reflux, demonstrate a paraureteral diverticulum, or show whether reflux is occurring into a duplicated collecting system or an ectopic ureter. In boys, radiographic definition of the urethra is important; accordingly, contrast VCUG is recommended for the initial work-up.

Because of concern that the VCUG is traumatic to the child, some parents question the need for a VCUG if the ultrasonogram is normal. However, ultrasonography is insensitive in detecting reflux; only 40% of children with reflux have any abnormality on the ultrasonogram. The VCUG should not be performed using general anesthesia, because the study is incomplete without a voiding phase and it subjects the child unnecessarily to the risk and cost of anesthesia. In selected cases, oral or nasal midazolam (up to 0.5?mg/kg oral route, 0.2?mg/kg nasal route), which causes anterograde amnesia and anxiolysis, may

Figure 530-4 DMSA renal scan showing bilateral photopenic areas indicative of acute pyelonephritis and renal scarring.

be used. We have found that this medication is efficacious and safe and provides an acceptable experience with VCUG. Vital signs are monitored and pulse oximetry is used; no anesthesiologist is present.

When the diagnosis of acute pyelonephritis is uncertain, renal scanning with technetium-labeled DMSA or glucoheptonate is useful. The presence of photopenia supports the diagnosis of pyelonephritis, and experienced radiologists can differentiate an acute from a chronic process. In approximately 50% of children with a febrile UTI, irrespective of age, the DMSA scan demonstrates parenchymal involvement. In children with grade III, IV, or V reflux and a febrile UTI, 80–90% show acute pyelonephritis. If the DMSA scan shows acute pyelonephritis, approximately 50% will acquire a scar in that site over the following 5 mo. However, if the DMSA scan is normal during a febrile UTI, no scarring results from that particular infection. Computed tomography is another diagnostic tool that can diagnose acute pyelonephritis, but clinical experience with DMSA is much greater.

If vesicoureteral reflux is present, a DMSA scan (Fig. 530–4) often is performed to assess whether renal scarring is present. The DMSA is the most sensitive and accurate study for demonstrating scarring. Excretory urography is not as sensitive as the DMSA scan in demonstrating renal scarring; in addition, visualization of the collecting system in infants and young children often is suboptimal, there is a slight risk of a contrast allergy, and it can take 1–2 yr for a renal scar to appear on the urogram. Computed tomography also has been used by some to evaluate the upper urinary tract because it is effective in demonstrating renal scarring (Fig. 530–5).

Frequently performed cystoscopies and measurements of urethral caliber in girls contribute nothing to the therapeutic decisions to be made in children with UTIs and are contraindicated. Narrowing of the female urethra was once postulated to be a contributing factor in the development of UTIs, but the urethras of girls with recurrent UTIs are not narrower than those of girls without infections.

Chapter 531 - Vesicoureteral Reflux

Vesicoureteral reflux is the retrograde flow of urine from the bladder to the ureter and renal pelvis. The ureter is normally attached to the bladder in an oblique direction, perforating the bladder muscle (detrusor) laterally and proceeding between the bladder mucosa and detrusor muscle, creating a flap-valve mechanism that prevents reflux (Fig. 531–1). Reflux occurs when the submucosal tunnel between the mucosa and detrusor muscle is short or absent. Reflux is usually congenital, occurs in families, and affects approximately 1% of children.

Reflux predisposes to renal infection (pyelonephritis) by facilitating the transport of bacteria from the bladder to the upper urinary tract. The inflammatory reaction caused by a pyelonephritic infection may result in renal injury or scarring, also termed *reflux nephropathy*. Extensive renal scarring impairs renal function and may result in renin-mediated hypertension, renal insufficiency or end-stage renal disease, impaired somatic growth, and morbidity during pregnancy. Reflux nephropathy once accounted for as much as 15–20% of end-stage renal disease in children and young adults. Currently, with greater attention to the management of urinary tract infections and a better understanding of reflux, it is much less common. Nevertheless, reflux nephropathy is one of the most common causes of hypertension in children.

Classification.

Reflux severity is graded using the International Study Classification of I to V and is based on the appearance of the urinary tract on a contrast voiding cystourethrogram (VCUG) (Figs. 531–2 and 531–3). The higher the reflux grade, the greater the likelihood of renal injury. Reflux severity is an indirect indication of the degree of abnormality of the ureterovesical junction.

Reflux may be primary or secondary (Table 531–1). Primary vesicoureteral reflux results from an anatomic deformity of the ureterovesical junction (see Fig. 531–1). Conditions such as bladder instability can precipitate reflux or worsen pre-existing reflux if there is a marginally competent ureterovesical junction. In the most severe cases, there is such massive reflux into the upper tracts that the bladder becomes overdistended. This condition, termed the *megacystis-megaureter syndrome*, occurs primarily in males and may be unilateral or bilateral (Fig. 531–4). In this particular condition, reimplantation of the ureters into the bladder to correct reflux resolves the condition.

Figure 531-1 Normal and abnormal configuration of the ureteral orifices. Shown from *left to right*, progressive lateral displacement of the ureteral orifices and shortening of the intramural tunnels. *Top*, Endoscopic appearance. *Bottom*, Sagittal view through the intramural ureter.

Figure 531-2 Grading of vesicoureteral reflux. Grade I: reflux into a nondilated ureter. Grade II: reflux into the upper collecting system without dilatation. Grade III: reflux into dilated ureter and/or blunting of calyceal fornices. Grade IV: reflux into a grossly dilated ureter. Grade V: massive reflux, with significant ureteral dilatation and tortuosity and loss of the papillary impression.

Approximately 1 in 125 children has a duplication of the upper urinary tract in which two ureters rather than one drain the kidney. Duplication may be partial or complete. In partial duplication the ureters join above the bladder and there is one ureteral orifice. In complete duplication the lower pole ureter drains superolateral to the upper pole ureter in the bladder. Reflux occurs in as many as 50% of cases into the lower ureter, which typically has a less competent valve, but in some cases reflux occurs into both the lower and upper systems (Fig. 531–5). With a duplication anomaly, some patients have an ectopic ureter, in which the upper pole ureter drains outside the bladder (see Chapter 532). If the ectopic ureter drains into the bladder neck, typically it is obstructed and refluxes. Duplication anomalies also are common in children with a ureterocele, which is a cystic swelling of the intramural portion of the distal ureter. In these patients often there is reflux into the associated lower pole ureter

Figure 531-3 Voiding cystourethrogram (VCUG) showing grade IV right vesicoureteral reflux with intrarenal reflux.

Figure 531-4 VCUG in male newborn with megacysticmegaureter syndrome. Note the massive ureteral dilatation due to high-grade vesicoureteral reflux. The bladder is very distended. There was no urethral obstruction or neuropathic dysfunction.

or the contralateral ureter. Reflux also typically is present when the ureter enters a diverticulum (Fig. 531–6).

In children with neuropathic bladder, as occurs in myelomeningocele, sacral agenesis, and many children with a high imperforate anus, reflux is present in 25% at birth. Reflux is seen in 50% of boys with posterior urethral valves. Clinically, reflux with increased intravesical pressure (as in detrusor-sphincter dyssynergia or bladder outlet obstruction) can result in renal injury, even in the absence of infection.

Primary reflux is found in association with several congenital urinary tract abnormalities. For example, 15% of children with a multicystic dysplastic kidney or renal agenesis have reflux into the contralateral kidney, and 10–15% of children with a ureteropelvic junction obstruction have reflux into either the hydronephrotic kidney or the contralateral kidney.

Reflux is an inherited trait. Approximately 35% of siblings of children with reflux also have reflux; the majority are asymptomatic. The likelihood of a sibling having reflux is independent of the grade of reflux or sex of the index child. Approximately 12% of

asymptomatic siblings with reflux have evidence of renal scarring. In addition, in women with a history of reflux, 50% of offspring have reflux. Consequently, many believe that siblings

TABLE 531-1 -- **Classification of Vesicoureteral Reflux**

Type	Cause
1. Primary	Congenital incompetence of the valvular mechanism of the vesicoureteral junction
2. Primary associated with other malformations of the ureterovesical junction	Ureteral duplication
	Ureterocele with duplication
	Ureteral ectopia
	Paraureteral diverticula
3. Secondary to increased intravesical pressure	Neuropathic bladder
	Non-neuropathic bladder dysfunction
	Bladder outlet obstruction
4. Secondary to inflammatory processes	Severe bacterial cystitis
	Foreign bodies
	Vesical calculi
	Clinical cystitis
5. Secondary to surgical procedures involving the ureterovesical junction	

of children with reflux should be screened even if they have not had a urinary tract infection (UTI). Screening with a radionuclide cystogram of all siblings 3 yr or younger and any sibling with a UTI is appropriate. Older siblings may undergo renal ultrasonography, and if an abnormality such as hydronephrosis or disparity in renal length is found, VCUG is recommended. Primary reflux is less common in African-Americans.

Clinical Manifestations.

Usually reflux is discovered during an evaluation for a urinary tract infection (see Chapter 530). In these children, 80% with reflux are female and the average age at diagnosis is 2–3 yr. In other children, VCUG is performed during evaluation of voiding dysfunction, renal insufficiency, hypertension, or other suspected pathologic process of the urinary tract. Primary reflux also may be discovered during evaluation for prenatal hydronephrosis. In this population, 80% of affected children are male and the reflux grade usually is higher than in females diagnosed with a urinary tract infection.

Diagnosis.

Diagnosis of reflux generally requires catheterization of the bladder, instillation of a solution containing iodinated contrast or a radiopharmaceutical, and radiologic imaging of the lower and upper urinary tract—a contrast VCUG or radionuclide VCUG, respectively. The bladder and upper urinary tracts are imaged during bladder filling and voiding. Reflux occurring during bladder filling is termed *low-pressure* or *passive reflux*; reflux during voiding is termed *high-pressure* or *active reflux*. Children with passive reflux are less likely to show spontaneous reflux resolution than are children who exhibit only active reflux. Radiation exposure during radionuclide VCUG is significantly less compared with contrast VCUG. However, the contrast study provides more anatomic information, such as demonstration of a duplex collecting system, ectopic ureter, paraureteral (bladder) diverticulum, bladder outlet obstruction in boys, upper urinary tract stasis, and signs of voiding dysfunction, such as a spinning top urethra in girls. Furthermore, the reflux grading system is based on the appearance on VCUG. Consequently, the VCUG is used in most centers as the initial study. For follow-up evaluation, the radionuclide cystogram is often preferred because of the lower radiation exposure (Fig. 531–7).

Children undergoing cystography may be psychologically or emotionally traumatized by the catheterization, or both. Careful preparation by caregivers or administering oral or nasal midazolam (for sedation and amnesia) before the study can result in a more acceptable experience.

A technique of detecting reflux without catheterization is termed *indirect cystography* and involves injecting an intravenous radiopharmaceutical that is excreted by the kidneys, waiting for it to be excreted into the bladder, and imaging the lower urinary tract while the patient voids. This technique detects only 50% of reflux cases. Another technique, avoiding cystourethrosonography, involves the use of ultrasonographic contrast medium, which is administered through a urethral catheter. The urinary tract is imaged with ultrasonography. The advantage of this technique is the absence of radiation, but its disadvantage is that it is less accurate than contrast VCUG and reflux cannot be graded.

After reflux is diagnosed, graded, and determined to be primary or secondary, it is important to assess the upper urinary tract. The goal of upper tract imaging is to assess whether renal scarring and associated urinary tract anomalies are present. Renal imaging can be performed by ultrasonography, excretory urography (intravenous pyelogram), or renal scintigraphy. Ultrasonography is a noninvasive method of evaluating the kidney, because it can demonstrate hydronephrosis, gross renal scars, and renal duplication (possibly with an obstructed upper pole system or a thin lower pole) and allows one to monitor renal growth over time. Only 30–60% of

renal scars are demonstrated with this technique. Intravenous pyelography involves

Figure 531-5 Various anatomic defects of the ureterovesical junction associated with vesicoureteral reflux.

injection of an iodinated contrast agent and provides good anatomic detail of the kidneys, but this study is performed infrequently in children at present. Approximately 90% of scars are demonstrated with this technique. Renal scintigraphy is usually performed with dimercaptosuccinic acid (DMSA), which demonstrates renal cortical detail well and is reliable in demonstrating nearly all renal scarring. However, it is less reliable than the other two studies in demonstrating renal anomalies such as hydronephrosis.

The child should be evaluated for voiding dysfunction, including urgency, frequency, diurnal incontinence, infrequent voiding, or a combination of these. In addition, bowel habits should be assessed. Children with bladder instability often require anticholinergic therapy and a voiding routine in addition to antibiotic prophylaxis.

After diagnosis, the child's height, weight, and blood pressure should be measured. If upper tract imaging shows renal scarring, a serum creatinine measurement should be obtained. The urine should be assessed for infection and proteinuria. Cystoscopy is of

Figure 531-6 Reflux and bladder diverticulum. The voiding cystourethrogram demonstrates left vesicoureteral reflux and a paraureteral diverticulum.

Figure 531-7 Radionuclide cystogram shows bilateral reflux.

no value in determining the prognosis or selecting treatment. Urethral dilatation is not beneficial.

Natural History.

The incidence of renal scarring or reflux nephropathy increases with the grade of reflux. With bladder growth and maturation, there is a tendency for reflux to resolve or improve over time. Lower grades of reflux are much more likely to resolve than are higher grades. For grades I and II reflux, the likelihood of resolution is similar irrespective of age at diagnosis and whether it is unilateral or bilateral. For grade III, a younger age at diagnosis and unilateral reflux generally are associated with a higher rate of spontaneous resolution (Fig. 531–8). Bilateral grade IV reflux is much less likely to resolve than is unilateral grade IV reflux. Grade V reflux rarely resolves. The mean age at reflux resolution is 6–7 yr. Reflux is unlikely to cause renal injury in the absence of infection. However, in situations with high-pressure reflux, as in children with posterior urethral valves, neuropathic bladder, and non-neurogenic neurogenic bladder (**Hinman syndrome**), sterile reflux can cause significant renal damage. Children with high-grade reflux who acquire a UTI are at significant risk for pyelonephritis and renal scarring.

Treatment.

The goals of treatment are to prevent pyelonephritis, renal injury, and other complications of reflux. Medical therapy is based on the principle that reflux often resolves over time and that the morbidity or complications of reflux may be prevented nonsurgically. The basis for surgical therapy is that in selected children, ongoing reflux has caused or has a significant potential for causing renal injury or other reflux-related complications and that elimination of reflux minimizes the likelihood of these problems.

Continuous antibiotic prophylaxis is the cornerstone in the initial management of children with reflux. Drugs commonly used for prophylaxis include sulfamethoxazole-trimethoprim, trimethoprim alone, and nitrofurantoin, generally administered once daily at a dose of one fourth to one third of the dose necessary to treat an acute infection. Prophylaxis is usually continued until reflux resolves or until the risk of reflux to the individual is considered to be low. The child's voiding and defecation habits are assessed, and voiding dysfunction and constipation should be treated (see Chapter 535). A urine culture should be performed if there are symptoms or signs of a UTI, or both. VCUG

Figure 531-8 *A*, Percent chance of reflux persistence, grades I, II, and IV, for 1–5 yr after presentation. *B*, Percent chance of reflux persistence by age at presentation, grade III, for 1–5 yr after presentation. (From Elder JS, Peters CA, Arant BS Jr, et al: Pediatric Vesicoureteral Reflux Guidelines Panel Summary Report on the management of primary vesicoureteral reflux in children. *J Urol* 1997;157:1846.)

(contrast or radionuclide) is generally performed every 12–18 mo. Periodic upper tract imaging should be performed to monitor the status of the upper urinary tracts. Follow-up evaluation should be performed at least annually, at which time the child's height, weight, and blood pressure should be recorded.

Medical management with antibiotic prophylaxis is considered successful if the child remains free of infection and has no new renal scarring and if the reflux resolves spontaneously. Breakthrough UTI, development of new renal scars, and failure of reflux to resolve are examples of failed medical management. Noncompliance, allergic reaction, or side effects to the prescribed medication may preclude medical management or lead to its failure.

Surgical therapy can be performed either through a low abdominal incision or endoscopically. Open surgical management involves modifying the abnormal ureterovesical attachment to create a 4:1 to 5:1 ratio of intramural ureter length:ureteral diameter. Numerous techniques have been described. Some involve opening the bladder (Politano-Leadbetter, Cohen transtrigonal, Glenn-Anderson), whereas others accomplish reflux correction by an extravesical approach

(Lich-Gregoir detrusorrhaphy). If there is a simple duplication anomaly, both ureters are reimplanted together, termed a *common sheath reimplant.* When reflux associated with severe ureteral dilatation, termed a **megaureter,** is corrected, the ureter must be tapered or narrowed to a more normal size to allow a normal length:width ratio for the intramural tunnel, and a corner of the bladder is attached to the psoas tendon, termed a **psoas hitch**. If the refluxing kidney is poorly functioning, nephrectomy or nephroureterectomy is indicated. Some clinicians are investigating the role of laparoscopic reflux correction via an extravesical approach.

Open surgical repair is generally performed in children who fail medical management, including those with breakthrough UTI, persistent reflux, and grade IV or V reflux. In general, blood loss is minimal and the hospital stay averages 2 days. The success rate in children with primary reflux is greater than 95–98% for grades I–IV, with 2% experiencing persistent reflux and 1% having ureteral obstruction that requires correction. The success rate is so high that many do not perform a postoperative VCUG unless the child develops clinical pyelonephritis. For grade V reflux, the success rate is approximately 80%. In lower grades of reflux, a failed reimplantation is most likely to occur in children with undiagnosed voiding dysfunction. In children with secondary reflux, the success rate is slightly lower than with primary reflux.

The technique of endoscopic repair of reflux involves injection of a bulking agent via a cystoscope under the ureteral orifice, creating an artificial flap-valve (Fig. 531–9). This technique has been termed the *subureteral injection.* The advantage of this technique is that it is a noninvasive outpatient procedure (under general anesthesia) with no recovery time. The success rate is 70–80% and is highest for lower grades of reflux. In October 2001 the U.S. Food and Drug Administration (FDA) approved the use of dextran microspheres suspended in hyaluronic acid (Deflux) for subureteral injection. In Europe the majority of children undergoing surgical correction of reflux undergo the STING. Other bulking agents are undergoing FDA-approved clinical trials.

The International Reflux Study showed that in children with grades III–IV reflux, after 5 years of medical or surgical therapy, similar results occurred with regard to new renal scarring and renal function. However, the incidence of clinical pyelonephritis was 2.5 times higher in the children managed medically and, at the end of the study, more than half of the medically managed children still had reflux.

Evidence-based guidelines pertaining to the treatment of reflux diagnosed after a UTI were published in 1997 by the American Urological Association (Table 531–2). These guidelines were written before an endoscopic FDA-approved implant became available. A guide for parents based on the report is available to assist the physician in discussing treatment options with the parents. The decision whether to recommend medical or surgical therapy is based on the risk of reflux to the patient,

TABLE 531-2 -- Treatment Recommendations for Vesicoureteral Reflux Diagnosed Following a Urinary Tract Infection*

Grade	Age (yr)	Scarring	Initial Treatment	Follow-up
I–II	Any	Yes/no	Antibiotic prophylaxis	No consensus
III–IV	0–5	Yes/no	Antibiotic prophylaxis	Surgery
III–IV	6–10	Yes/no	Unilateral: antibiotic prophylaxis	Surgery
			Bilateral: surgery	
V	<1	Yes/no	Antibiotic prophylaxis	Surgery
V	1–5	No	Unilateral: antibiotic prophylaxis	Surgery
V	1–5	No	Bilateral: surgery	
V	1–5	Yes	Surgery	
V	6–10	Yes/no	Surgery	

** Summary of guidelines developed by American Urological Association; age refers to age at diagnosis.*
